Lumleian Lectures
ON
EPILEPSY.

The Lumleian Lectures, 1928, delivered at the Royal College of Physicians of London

BY JAMES COLLIER, M.D. LOND.,
FELLOW AND COUNCILLOR OF THE COLLEGE; PHYSICIAN AND LECTURER ON MEDICINE, ST. GEORGE'S HOSPITAL.

LECTURE III.*

Delivered on March 29th, 1928.

THE clinical features of epilepsy have been so brilliantly and fully described by so many writers, from very ancient times downwards to the present day, as to forbid any recapitulation of them in these lectures. There are, however, some details to which I wish to call attention, because they have a bearing upon the argument which I have raised as to the cause of epilepsy, and because some of them have recently received important attention in the literature of this subject.

MENTAL DETERIORATION.

Though commonly met with in epilepsy, mental deficiency and progressive mental failure are no necessary associates of this disease. For the highest mental attainments throughout a long life have often accompanied a recurring epilepsy of life-long duration. It is most commonly seen in epilepsy commencing in childhood, but it may accompany epilepsy that comes on at any time up to old age. It is often seen in the organic epilepsy of childhood both from that associated with agenesia of the brain and that from local vascular and encephalitic lesions. It seems to have no relation either to the nature or the severity or to the frequency of the epileptic attacks, and one meets with progressive mental degeneration in patients in which the attacks are neither severe nor frequent, and it is often completely absent in patients with severe and frequent attacks. It has been said to occur more often with frequent minor attacks, but this is certainly not the case. Gowers emphasised this fact years ago, and the description of pyknolepsy which I gave in my last lecture proves it. In some cases the mental deterioration precedes the appearance of epileptic manifestations by months or even years. From these facts it is quite clear that mental deterioration in association with epilepsy is certainly not caused by the occurrence of fits. Gowers places it in exactly the right position when he says: "Mental failure is determined by a factor which is related to the ultimate cause of the disease and not to the developed characters of epilepsy." Put in other words, this means that there is another factor besides the epilepsy-producing factor in those cases which present mental deterioration. As the fundamental causes of mental deterioration in such conditions as dementia præcox and other alien disease are at the present time held to be disorders of metabolic and endocrinic function, by which the nervous system is deprived of activators or disturbed by unusual products of metabolism and its function thereby progressively deranged and abrogated, it is easy in arguing that epilepsy is a metabolic disorder to add a further metabolic disorder, similar to that which is hypothesised as the cause of dementia præcox, in order to account for the association of mental deterioration with epilepsy in some cases. I have already referred to the clinical association of epilepsy with dementia præcox. It is unlikely that a metabolic disorder would be exactly the same in every subject. It is likely that the different aspects which epilepsy and the allied maladies which I have here mentioned may present are determined by differences, sometimes quite slight, in the underlying metabolic disturbances.

* Lectures I. and II. appeared in THE LANCET of March 24th and 31st respectively.

JACTITATION AND MYOCLONUS.

I have already spoken of these phenomena in my first lecture. I mention them again to emphasise that the two conditions are essentially the same, for I have watched a patient in which the simple jactitation passed into the bulky and shock-like myoclonus, and I entirely support Muskens in his recent opinion that myoclonus-epilepsy is not a blend of two diseases—not a coincidence of epilepsy and myoclonus in the same subject, but that myoclonus is a characteristic manifestation of epilepsy and simply an exaggeration of jactitation. Jactitation is a common phenomenon of epilepsy. It is often seen in that form of epilepsy which goes under the name of infantile convulsions. It is characteristic of the epileptic state of uræmia. It is a common event as heralding an impending attack in idiopathic epilepsy, but it may occur from time to time during the interparoxysmal period. It may occur continuously throughout the whole of the interparoxysmal periods except during the deepest sleep and then constitutes the clinical entity of "epilepsia continuans." Perhaps it may occur alone and present a picture of continuous epilepsy without paroxysms. In its major form it is usually continuous and associated with convulsive paroxysms and has been called "myoclonus-epilepsy." These are the only manifestations of epilepsy which can occur without cessation and without limit of duration. These two conditions are here reported, I think, for the first time, occurring in one limb together with local convulsion and local paralysis in a patient in whom the existence of a local lesion of the brain, though presumptive, was almost unchallengeable.

EPILEPTIC PARALYSIS.

Todd's paralysis, called by him "epileptic hemiplegia," and afterwards "post-epileptic paralysis," may occur with any form of epilepsy whether idiopathic, organic, or symptomatic, but it is more evident in connexion with local attacks. It was explained by Todd as a condition of exhaustion following the severity of the convulsion, but it soon became evident that it did not necessarily follow even the most severe convulsion or series of convulsions, and that it may be absolute after a very slight convulsion. Hughlings Jackson referred it to a condition of inhibition, and Gowers pointed out that it was apt to follow upon a local sensory attack commencing in the limbs. Except in its mildest degrees Todd's paralysis is accompanied by the well-known signs of involvement of the pyramidal system. I wish to emphasise as a fact that simple paralysis is one of the essential manifestations of epilepsy, not dependent upon, nor in train of, any other epileptic incident, and that it may be the sole manifestation of an epileptic attack just as the paralysis of migraine usually is the sole manifestation of the migrainous attack in which it occurs, I have had two epileptic patients who had many attacks of sudden onset of local paralysis which was absolute for a short time and soon passed away. Now and again these attacks of simple paralysis were accompanied by a local aura which clearly revealed their nature, but most often the paralysis constituted the whole of the attacks. Both these patients had occasional attacks of severe general convulsion.

I will now give the details of a fascinating case which illustrates the nature of epileptic paralysis, and which shows further details of interest which indicate that our conception of epilepsy should be a very broad-minded one. I must preface this case by saying that skiagraphic examination showed a densely opaque, very sharply defined object, about the size of the top of my thumb in the subcortex of the left central region, just beneath the centre for the right hand. It was probably a heavily calcified tuberculoma.

This patient was a woman who at the age of 17 years commenced to have general and somewhat severe epileptic attacks at night. These occurred with a very regular frequency of once every six months for the next 20 years,

665273

with the exception that during her three pregnancies she had never had an attack. In a few of her attacks it had been noticed that the attack began on the right side and this had struck the attention of her husband, because nearly all of her attacks began on both sides and all over. Her health had otherwise been unimpeachable. Here was a very typical condition of idiopathic epilepsy, one would have thought, with its strictly nocturnal incidence, regular periodicity, and cessation during pregnancy. At the end of 20 years, in 1922, this patient had a difference with her husband and was for some days distraught with grief, and during this time she had an attack of local convulsion in the right hand without any impairment of consciousness, and this was followed by other attacks of like nature with increasing frequency, until when I first saw her she was having attacks at regular intervals of 20 mnutes night and day, and in this condition she was admitted into the National Hospital.

The attacks commenced by the patient calling out that she had "horrible pain" in the right hand which showed slight tonic spasm followed by clonic spasm of no great intensity, which lasted some three minutes. The spasms spread slowly up the arm, but never higher than to cause a partial involvement of the deltoid with slight abduction at the shoulder. Never did the convulsion spread to the face, tongue, trunk, or lower extremity. Nor was there any loss of consciousness nor aphasia. There were never at any time any signs of raised intracranial pressure, nor were there any objective disturbances of sensibility, even in the right hand.

Partly because I had surgical measures in my mind, and partly because Dr. Wyllie, who was then my house physician, begged that he might be allowed to continue investigations upon these attacks, and that I should not spoil so beautiful a case for demonstration by medicinal treatment, this patient received no treatment at all. In a little while, with the regular continuance of the attacks, it was noticed that the hand and arm were weak between the attacks, and then were completely paralysed between the attacks, the paralysis spread slowly to the tongue and face, but there was never the least trace of aphasia, and it spread also to the leg, foot first. In the course of a fortnight this patient had developed an absolute and stony hemiplegia with all the signs of pyramidal involvement well marked, notwithstanding that there had never been the least sign of convulsion either in face, tongue, or leg. So far as these regions was concerned, the condition was one of simple epileptic paralysis as the isolated result of the epileptic attacks. Some little time later the attacks suddenly ceased and thereafter the paralysis of tongue, face, leg, and arm in that order lessened and completely disappeared, the abdominal reflexes returned, and even the extensor response in the plantar reflex had changed to normal by the time she left hospital six weeks after her admission.

Six years later, just before Christmas of last year this patient walked into my consulting-room. She had had three fits in the six years of her old general nocturnal type. She had recently had a fit in the daytime, commencing in the right hand and followed by weakness, and had come to me in fear of a repetition of the events of 1922. I found that she had for some months been dragging the right leg in walking and there was a definite extensor response in the right plantar reflex. Some extension is now occurring from her local lesion.

I wish to call attention in this case particularly to the amazing effect which a strong psychic disturbance had upon even an organic epilepsy. It changed the type of the attack from an infrequent general and nocturnal attack to a very frequent and succinctly local attack. No one can doubt the influence of strong emotional factors upon every variety of epilepsy, and it is likely that such influences act by disturbing metabolism. If this case had only been treated by psychotherapeutic measures, what a grand success it would have made for psychotherapy in epilepsy.

This patient called out with horrible pain with the commencement of each local attack. There was no spasm as would cause any such pain, for I have repeatedly seen much more severe local fits which caused no discomfort to the patient. Therefore this pain is likely to have been a sensory manifestation of the local attack—in other words, an aura. But it could not have arisen in any higher structure than the optic thalamus, and yet the lesion in this case was undoubtedly subcortical. This I submit is an expression of a general principle that may be applied to epilepsy, that the disturbance of the cortex may secondarily give rise to phenomena which strictly belong to lower regions of the nervous system. When Spiller and others use the term "subcortical epilepsy," they do not prove nor do I think they mean that epilepsy can result from other than a cortical disturbance, but that the manifestations belong to the presumable function of subcortical levels.

Lowering of Blood Pressure.

I have argued that a lowering of blood pressure is a characteristic manifestation of the attacks of epilepsy and of the allied maladies which I have here referred to. Its constant occurrence in the attacks of migraine and in vaso-vagal and syncopal attacks is unchallengeable. But in epilepsy it has been, and still is, a highly controversial matter. The ancients held for vaso-constriction in the brain as the immediate cause or, at any rate, the accompanying feature of the epileptic attack, and so do some of the moderns—Foerster, for example, in spite of the work of Leonard Hill and the more recent investigations of Florey, which prove almost beyond argument that there is no vaso-constrictor mechanism for cerebral blood vessels and that if there were it could have little or no influence upon local cerebral circulation. Bossard and many of the French School hold that there is an initial fall of blood pressure, and with them I agree. Though Foerster in his many experiences of the change of colour of the exposed brain at the onset of convulsion is quite sure that vaso-constriction occurs, yet Foster Kennedy's description of this same event convinces me to the opposite effect. He says:—

> "We were looking at the surface of the brain exposed by operation, when a sudden pallor occurred and the patient began to move in general convulsions, but the pallor was no sooner remarked by us than it was replaced by engorgement of the surface and bulging of the brain, due to the general venous engorgement produced by the convulsion."

This does not seem to me to be the description of vaso-constrictor action, but rather that of a sudden drop of blood pressure followed by a rise resulting from the convulsion. I do not wish to place lowering of blood pressure as the immediate cause of the epileptic attack nor of any of the epileptic manifestations except the blanching of the brain and the skin, though this may in truth be the real relation, but I think it is a common manifestation of the commencement of the epileptic attack, and I wish to bring epilepsy into line with the other epilepsy-like maladies in which such lowering of blood pressure does occur.

The Site of Origin and Nature of Epileptic Processes.

The site of origin of epilepsy seems definitely confined to the cortex of the cerebral hemispheres, since every local lesion that I have seen productive of epilepsy has been in or near the convolutions or has been in such a position as allows of some secondary process, such as œdema or ventricular cystation, to affect the convolutions. Thus, a tumour of the pons by obstructing the aqueduct may give rise to hydrocephalus, and this in turn may produce fits, either general, unilateral or local. I have at the moment of writing a case of a neurofibroma growing from the right eighth nerve underneath the tentorium with a four years' history and a recent advent of right-sided convulsions, but there is intense papilloedema, and it is obvious that tissue dislocation at the foramen tentorii has produced distension of the lateral ventricles, of which the epilepsy is an expression.

Some authorities, however, hold an opposite opinion. Spiller, for example, writes: "There can be no doubt that, even in man, epileptic attacks may be caused from subcortical centres. These attacks are chiefly of tonic character, but clonic spasms have been observed," and after discussing the names, "spastic epilepsy" used by Knapp, "extrapyramidal epilepsy" used by Sterling, and "striate epilepsy" used by Wimmer, and finding these unsuitable employs the term "subcortical epilepsy" for tonic fits in which pyramidal signs are absent, and he proceeds to describe two cases which were not examined pathologically, but which were really of extreme

clinical interest. Spiller remarks several times in his paper how like these two cases were to cases of tetany, with the carpo-pedal spasms, the severe cramping pain, the hot paræsthesiæ and the advent of the fits on handling of the limbs. But it does not seem to strike him as it strikes me, very forcibly, that his two cases were indeed very beautiful examples of tetany. They did not present any feature which is not well known in tetany. In one of his cases the fits were confined to the hand and leg of one side which were paretic, but so high an authority as Frankel-Hochwart has reported two cases of spasm confined to one side, in which all the true reactions of tetany were present. There is one point of advantage in the description of these cases by Spiller, and it is to bring forcibly to our notice that there is a class of case which is called epilepsy by one authority and tetany by another, and to suggest, as I have already done, that these maladies are not very far separated, and that they may merge clinically the one into the other.

The upholders of a subcortical origin for some epilepsies maintain their arguments rather from the standpoint that the symptoms of tonic fits are such as they would expect to result from disturbance of function in the basal ganglia, because they show in some degree the same kind of rigidity as do lesions of the basal ganglia, rather than that they have seen these fits result from proved lesions of the basal ganglia.

We are here on very debatable ground, for no one will deny that in the disease lethargic encephalitis the strangest varieties of paroxysmal phenomena often appear, and this disease affects the basal ganglia in particular. Nor can any one affirm that epileptic manifestations or anything resembling them, result with any frequency from this disease. According to a theory of epilepsy at present much in vogue, which I shall refer to later on, a disturbance of the cerebral cortex may give rise to a secondary disturbance in any of the lower levels of the nervous system and the symptoms resulting, may correspond with our ideas of what disturbance of the lower centres should cause, but this disturbance of lower centres, though it be the only phenomenon exteriorised, does not prove that the starting-point of the attack is in such lower levels.

I will now call attention to a newly described symptom of epilepsy which is held to have its origin in the putamen and optic thalamus. It was described by Knapp in 1919. The case is one of the usual type of general epilepsy in a child. The fits which have occurred for years perhaps becoming increasingly frequent. Speech becomes slow and difficult and the limbs and trunk become rigid and show perversity and slow spontaneous movements, and there is facial grimacing and emotional over-activity. The picture comes to exactly resemble that of the malady which Gowers called "tetanoid chorea," and which Wilson has now named hepato-lenticular degeneration, in which there are conspicuous lesions in the lenticular nucleus. And Knapp says here, too, there is a lesion in the same position. But Knapp treated his patients with bromides and stopped the fits and little by little all the symptoms of the lesion of the lenticular nucleus disappeared and the patient resumed the normal. He stopped treatment. On came the fits again and on came the same lenticular nucleus syndrome. This is amazing, and it will remind you of my story of epileptic paralysis becoming complete for weeks and remitting entirely for years with the cessation of the fits.

Here is a characteristic case of Knapp's syndrome which was recently under my care which convinces one of the truth of Knapp's picture and leaves one in a position to choose whether the cortex or the basal ganglia were primarily at fault.

A boy, aged 12 years, of precocious intelligence and good physical development, in whose family there had been several cases of epilepsy, was brought to me suffering with frequent fits of two years' duration. He had had a very few general fits, but nearly all his fits, which often happened a dozen times in one day, commenced in the left foot with spasm. If he was thinking about it when the fit started he could nearly always stop the fit by a powerful dorsiflexion of his foot, but if he was absorbed in any act or event and let the fit get as high as his knee, he had no power to arrest it and it spread to the arm and became general with loss of consciousness. He could excite a fit at will by tickling the sole of the foot, and we were able to do so also by almost any form of stimulation of the foot. He was successfully treated for the time at the National Hospital and returned to school where, some time after, he had a severe bout of frequent fits and was readmitted to hospital mentally very dull with a speech so slow and clumsy as to be almost unintelligible and with great spasticity of all the limbs with slow spontaneous movements and facial grimacing. The clinical aspect was just that of lenticular degeneration and the diagnosis was changed to one of organic disease of the basil ganglia. Treatment with luminal stopped the fits and within three weeks of their cessation this boy had returned to the normal. He subsequently went back to school and carried on well for some five months, when a sudden advent of severe fits proved fatal so rapidly that the parents had no opportunity of communicating with me, nor did I hear of the event until some weeks afterwards.

Now there was nothing about this case which suggested more than a familial idiopathic epilepsy of local and reflex type until a severe exacerbation of the attacks resulted in a lenticular syndrome so severe that we never dreamed of its recovery. Yet recovery was complete and remained so long as the convulsions were kept in abeyance. There was nothing in the nature of these fits to suggest anything but a cortical origin. They were local tonic-clonic fits without loss of consciousness, which could be arrested by strong voluntary effort and which could be produced reflexly—the very type of what we consider to be epilepsy of cortical origin.

In his recent study upon epilepsy Foerster expresses the opinion that every part of the nervous system can be the starting-point of an epileptic attack. It is certain that in horses and horned cattle the stimulation of cicatrised wounds, especially of the horns, hoofs, and withers, may give rise to epileptic fits, and a very few parallel instances in man are recorded by Gowers. This fact, however, does not necessarily mean more than that the immediate excitant of the fit may be peripheral, for the point of origin may be cortical. Gordon Holmes, writing upon epilepsy from local lesions of the brain in the Savill Memorial Lecture for 1927, points out how nearly every local epilepsy of a limb comes to being a reflex epilepsy. The patient will wear his hand in his pocket and take various other measures to protect his epileptic limb from jars and knocks and sensory stimulation lest a fit should result, I entirely agree, and would extend Holmes's principle to the local epilepsies without organic lesion of the brain. I have more than once caused the first reflex fit in an epileptic foot in my endeavours to investigate the plantar reflex, and often the patients have begged me to desist, for they felt that a fit would come on if I continued. Gowers reported the case of a man who had his left forearm painfully bruised in an accident. A few days later a local fit occurred in this arm accompanied by pain similar to that felt after the accident and these attacks continued, but later on this patient developed headache and papillœdema and signs of a local lesion of the right central convolutions. The injury to the arm had merely served to excite the first attack and had perhaps determined its local colour—the pain. In the vast literature upon reflex epilepsy many examples have been recorded in which fits due to a lesion of the brain could be brought on by peripheral stimulation, and therefore there seems to be no difficulty in accepting a cortical origin for all reflex epilepsy.

In the spinal animal and in the decerebrate animal tonic-clonic spasms can be elicited by the administration of convulsant poisons. Therefore, the origin of epilepsy-like fits in the spinal cord and brain-stem is theoretically possible. But if such events occur as spontaneous clinical phenomena in man they must be so rare as to have escaped the observation of most of the workers on epilepsy. The contention of Horsley and others that the cerebral cortex is necessary for the expression of the clonic component of the

epileptic fit is negatived by the work I have just mentioned, but it has recently been revived by Dandy, who asserts that he was unable to produce anything but tonic spasms in the decorticated dog. The ancient experiments of Nothnagel, Schroeder, and others of the production of epileptic manifestations by irritation of the pons and medulla is open to the objection that afferent paths were likely to have been stimulated and a reflex epilepsy produced in this way.

The oft-recurring statement which one finds in the literature that hæmorrhage or tumours of the pons or cerebral peduncles have repeatedly caused epileptic attacks either unilateral or bilateral, is unfortunate. For the spasms resulting from the tearing-up of the central nervous system by hæmorrhage or by any other mechanical disturbances have nothing to do with epilepsy. Tumours of the pons and of the peduncles so easily cause distension of the ventricles and high intracranial pressure, both of which are potent causes of convulsion. When Foerster describes the epilepsy typical of these lesions with bilateral tonic spasm, head retraction, opisthotonus, tonic ocular spasm and stertorous breathing, I call to mind the many cases in which I have seen this picture, where the tumour has been just anywhere you please, provided the ventricular distension and high intracranial pressure were present. In answer to Spiller's summing-up, "that there can be no doubt that even in man epilepsy can be caused from subcortical centres, and these attacks are chiefly of tonic character," I would reply that this may be so, but that the clinical examples must be very rare. Most of the recorded examples are unconvincing and admit of another explanation and, lastly, convulsion consisting of tonic spasm alone is common in every variety of epilepsy. It is least common in organic epilepsy and most common of all in the minor attack of epilepsy.

The cortical origin of epilepsy is suggested by the readiness with which convulsion can be produced by electrical and chemical stimulation of this region and, in connexion with the latter, I may mention two clinical facts which suggest that epileptic fits are sometimes caused by surface irritation. The first example is that of spontaneous subarachnoid hæmorrhage from a leaking aneurysm of the circle of Willis. In this condition one meets with fits, not when the blood is first effused and not when the symptoms are acute, but after days or weeks when the remains of the blood are turning brown or yellow. These attacks seem never to recur after the patient recovers. The other example is that of uræmic convulsions. No one, I think, who has witnessed the immediate cessation of severe uræmic convulsions, when the cerebro-spinal fluid is drained by lumbar puncture, can have any other impression than that the fluid withdrawn contained some irritant which was causing those convulsions.

The exteriorisation of the convulsive phenomena of epilepsy is presumably by the pyramidal systems on the ground of the many reported cases in which the advent of a vascular lesion interrupting the pyramidal path on one side in a case of general epilepsy has caused the cessation of convulsion on the corresponding side. But there is certainly another path, for Economo and Karplus have shown that complete division of the pes pedunculi on both sides does not prevent the occurrence of cortically induced convulsion, and therefore such convulsion must be exteriorised through some mediate strio-tegmental path. There is sound clinical evidence in support of these experiments. But when Wimmer, Dandy, and the upholders of subcortical epilepsy in general contend that the clonic element in convulsion belongs to, and is exteriorised by, the pyramidal system, whereas the tonic spasm is essentially connected with the mediate strio-tegmental paths, we must, I submit, follow Gowers and consider that though clonic and tonic spasm are occasionally dissociated in epilepsy, yet they are so commonly associated and blend the one into the other by such minute gradations as make it difficult to believe that they are not expressions of disorder in the same anatomical substratum. But in this consideration, as in so many of the problems of neurology, we are so apt to forget that the nervous system habitually acts as a whole and not in terms of its individual anatomical structures. Not even in the simple activities of the lowest levels is isolated activity clearly seen, and in the higher levels, and especially in the highest level of the cerebral cortex, it is probable that functional activity which we at the present time presume occurs locally, coinvolves functional activity throughout the whole of that level and possibly throughout the whole of the nervous system.

The Nature of the Epileptic Process.

The most commonly occurring feature in all epileptic symptoms is loss of function. Only with simple epileptic jactitation, and sometimes with a peripheral aura occurring alone, does one see no loss of function. So far as the highest functions of the nervous system which we are accustomed to refer to the cerebral cortex are concerned, the phenomena of epilepsy are, with one exception, unvaryingly those of loss of function. In the epileptic attack there are no counters of thought, but consciousness is lost or impaired. There are no elements of speech, but speech is lost. There is no sensation of an act, but simply of movement. The hallucinations of special and common sensibility which occur commonly have nothing to do with memories of life, but they are vague, crude, and undefinable; tastes and smells, and sensations and visions, which are never experienced except in the epileptic attack. The movements which occur in convulsion have no comparison with those of everyday life if we except the conjugate deviation of eyes and head, they are characterised by a purposeless discord. Even the most narrowly localised convulsion has no counterpart in ordinary usage. The whole train of positive phenomena do not seem to belong to the highest levels of the nervous system.

The one exception is the occurrence of the "dreamy state" and of highly organised hallucinations of hearing and of vision. So far as local lesions of the brain are concerned, these curious psychic states and complex hallucinations are only met with lesions of the uncinate lobe as Holmes has recently emphasised. Local lesions of the auditory and visual convolutions never produce more than crude and foreign hallucinations. I would go farther than Holmes, and say that on clinical grounds all the complex and highly organised hallucinations are part of a "dreamy state," and they are met with only in fits with an uncinate origin. The clinical reasons are the common association of both visual and auditory hallucinations with an aura of taste and smell. If this be so, it is interesting to consider why the uncinate lobe alone is responsible for highly organised hallucinations. Is it because the cerebral hemispheres are phylogenetically mere appendages of the organ of smell, and is it connected with that power which smell is said to have above all other stimuli in suddenly and vividly exciting that variety of cerebral activity which is known as memory?

The epileptic attack often consists in loss of function only as in the simple loss of consciousness which constitutes so many minor attacks, and as in the simple falling attacks, and the simple attacks of paralysis, and more rarely in the auditory attacks with sudden sense of stillness and silence, and the visual attacks with hemianopia only, which Gowers records and of which I have seen two examples. From these considerations the opinion is widely held nowadays that the essential element in the epileptic attack is a sudden loss of function, local or general, in the higher levels of the nervous system, and that all positive phenomena which occur, such as hallucinations and convulsions, are of the nature of "release" phenomena in lower centres. This idea has been largely written upon by Hartenberg and is known as Hartenberg's theory. It is really a very

old hypothesis, for Hughlings Jackson explained the "dreamy state" and highly organised hallucinations which may follow an olfactory aura as the result of loss of control, from the discharge causing the less elaborate sensation, and he also attributed post-epileptic automatism and post-epileptic hysteria to the release of lower centres from control consequent upon the "exhaustion" of the discharge. Gowers placed inhibition, which he said was only a physiological term for arrest of action, in a very high place as the initial phenomena in most epileptic attacks.

Hartenberg's hypothesis seems to be the best working theory for the explanation of epilepsy, though its terms, "inhibition" and "release phenomena," like the "discharge" and "excitation" of the older theories, seem inadequate physiological words appended to very obvious phenomena, of the real nature of which we know at the present time almost nothing. Upon this theory it is interesting to speculate at what levels the release phenomena occur. Gordon Holmes, though he still speaks of excitation and irritation, confines the site of origin of convulsion and sensory disturbance to the cerebral cortex, but limits it to the more lowly elements, afferent or recipient, and seeks thus to explain the simple and crude sensations and the purposeless discord of the movements. Martin considers that the convulsion does not arise in the cortex, and arguing from Cobb's experiments that the tonic spasm of epilepsy is a true tetanus and not a postural tone increase as are most cerebral rigidities, and also from the similarity of the positions assumed by the limbs in epileptic attacks with those obtained reflexly below the lesion when the spinal cord is transected in man, and from the fact that epileptic convulsion, both tonic and clonic, occur in very young, when he presumes the cerebral cortex not to have any function, he states a case for epileptic convulsion as a release phenomenon at the low level of the brain-stem and spinal cord.

I would here suggest, if the theory of "release" be the correct theory, that some of the release phenomena must be of the negative order. Knapp's syndrome, of which I have given you an example, must be due to a loss of function in the lenticular region. The complete loss of sensibility to all forms of stimulation following upon sensory attacks recorded by Holmes must involve complete loss of function at a level not higher than the thalamus. The curious minor attack in which the patient always falls from the standing position in a constant direction, either always forwards or always backwards, and never sideways, so that his forehead or occiput reach the ground first, must be due to a sudden arrest of function at some cerebellar level. Diplopia occurring early in the epileptic attack has been recorded by the most able observers, though it is a rare event and I have never seen it. It cannot in my conception result from any higher level than that of the oculomotor nuclei. The most commonly occurring and obvious of the release events is of spinal level—that of the sphincters. It seems certain, therefore, that as the result of the disturbance of cortical function and possibly in some cases as a primary event, both positive and negative phenomena occur in epilepsy which have their pattern determined by the function of any of the lower levels of the nervous system, and if a sudden lowering of blood pressure be a constant early manifestation of the epileptic attack, as it is of the syncopal attack, this may be described as a negative phenomenon at the level of the medulla.

The headache, vomiting, sleepiness, and general feelings of illness which often follow the epileptic attack call for some comment, since they bear no constant relation to the nature or severity of the attack. They may follow even in severe degree upon a minor attack of a few moments' duration. On the other hand, there are rare cases in which, after the most severe and prolonged general convulsion, consciousness is restored suddenly and the patient is able at once to carry on what he was doing as if nothing had happened. These post-epileptic symptoms must therefore be dependent upon some factor which is now present and now absent and not upon the attack itself. The nature of the headache and its habit in some cases of ceasing suddenly if vomiting occurs, or of ceasing when sleep occurs, and of becoming intolerable if sleep is prevented remind one of migraine and suggest to me that actual swelling of the brain does occur sometimes in the epileptic attack as it certainly does in the attack of migraine, and that this swelling is responsible for these symptoms. Gowers drew attention to the comparative mildness of such symptoms in organic epilepsy even after severe general convulsions as compared with idiopathic epilepsy, and stated that he had never met with post-epileptic vomiting in organic epilepsy.

Treatment.

My experience in the treatment of epilepsy urges me to make a few remarks upon this side of the subject for the reason that I hold views which are not universally accepted, rather than that I have anything fresh to announce. There can be no doubt that the less the life of an epileptic person departs from that of a normal person, the better will be the result of medicinal treatment and the more hopeful the outlook in the end. Therefore, in every case of epilepsy where it is possible, education, occupation, and recreation should continue without restriction whatsoever. So often one sees in a case of epilepsy commencing during school years, rest, removal from school, and cessation of education advised without thought of the fact that a state of mental activity and attention and interest or of physical activity are powerful repellants of the advent of the epileptic attack, so that the habitual epileptic will seldom, or never, have an attack when he is at work. On the other hand, the discouragement of hopes, the abrogation of play, and the despondency wrought of inanition and the feeling that something is wrong and that he is different from other people will produce an effect upon the incipient epileptic that medicinal treatment will scarcely remedy. Even excitement, which is well known as a cause of fits, need not be interfered with. It is better to fortify the patient with a preventive dose before any excitement is to happen and let him go through with it. States of bodily peculiarity and ill-health have so often been held responsible for the onset and upkeeping of epilepsy and the treatment of these considered essential for the betterment of the malady, such as digestive troubles, constipation, ileal stasis, nasal obstruction, and so on. With the single exception of rickets I have never found any such conditions to be real factors, nor have I witnessed their betterment to be accompanied by any improvement in the epilepsy. Some of them are certainly expressions of the same fundamental metabolic state which causes the epilepsy.

Since the introduction of the malonyl-urea compounds for the treatment of epilepsy, of which luminal may be taken as a type, in 1912 their very great value has gained universal acceptance, and the use of luminal has largely supplanted that of the bromides. It has much the same effect and does not cause acne nor dyspeptic symptoms, but there seem still to be some cases which do better on bromides. Whichever drug is used there seems to be no advantage in administering it more than twice a day, nor in using any but moderate doses—up to grs. 1½ of luminal and grs. 20 of sodium bromide. The whole purpose of these remedies seems to be to anticipate and prevent a fit. Therefore it seems useless to give these drugs for the treatment of nocturnal epilepsy except in a single dose at night, or for diurnal epilepsy except in a single dose in the morning, and for epilepsy that occurs both by day and by night, both night and morning. In so much as the attacks occur at regular times and can be anticipated one hour by a dose of the remedy, the epilepsy can be the more successfully treated. The only other remedies which really influence epilepsy are zinc salts and belladonna. There are a few rare cases in which one or other of these remedies are of signal benefit, and these are

generally cases in which both luminal and the bromides have failed.

Status epilepticus, however, is utterly rebellious to the remedies which I have mentioned. There is in this condition the utmost necessity to preserve the bodily nutrition and strength by careful watering and feeding and by the use of stimulants, and this administration should be from the first by the nasal tube. Any remedy which has any depressant effect, such as luminal, bromides, morphia, or chloroform, does more harm than good. There is, however, one newly introduced remedy which was first used at the National Hospital by Dr. Arnold Carmichael, who was then resident medical officer, which is of signal value in the treatment of status epilepticus and it is paraldehyde. This is a stimulant as well as having a most powerful action in checking convulsion. It can be given in large doses, up to eight drachms without ill-effect, and it is readily absorbable from the rectum when mixed with an equal quantity of olive oil. With this remedy I have saved many patients in status epilepticus whose condition was so desperate as to make me believe that they must necessarily have perished in former days when I did not use paraldehyde. I would further recommend the use of paraldehyde in any epilepsy whatsoever in which convulsive attacks are of frequent occurrence.

In conclusion, I may point out that the medicinal treatment here outlined for epilepsy is applicable to every form of epilepsy, idiopathic, organic, and symptomatic, and also to those maladies, migraine, vaso-vagal and syncopal attacks, and so forth, which I have here referred to as closely related to epilepsy.

THE VALUE OF BISMUTH THERAPY IN SYPHILIS.

BY C. LEVADITI,
OF THE PASTEUR INSTITUTE, PARIS;
AND
L. FOURNIER,
OF THE HOPITAL COCHIN.

WRITING in THE LANCET (1927, i., 148 and 199) on the use of bismuth in the treatment of syphilis, Dr. T. Anwyl-Davies came to the following conclusion:—

"Bismuth in some way—possibly by some tissue reaction—merely inhibits the disease instead of having a direct curative action on the infection. These experiments suggest that the therapeutic effect of bismuth may not be as satisfactory or as permanent as one might desire."

He bases this opinion on references from the work, both experimental and clinical, of various authorities, especially that of Kolle and his collaborators. According to Kolle,[1] bismuth does not destroy the *Spirochæta pallida*, but cures the specific lesions by producing certain tissue reactions which arrest the multiplication of the parasites. While in no way questioning Dr. Anwyl-Davies's sincerity, nor under-estimating the value of his contribution, we must disagree with him profoundly on several points, and must insist that, by presenting the problem of the therapeutic efficiency of bismuth as he did, he has cast discredit upon a method whose benefits have been universally admitted.

The Case against Bismuth.

Kolle[2] bases his opinion on the following results: rabbits inoculated with a syphilitic virus (Truffi's or Nichols's strain) remained protected from infection for at least 109 days after receiving intramuscular injections of insoluble bismuth derivatives, while those which received injections of soluble salts contracted the disease.

A second series of experiments, however, gave results which to him and to Dr. Anwyl-Davies seemed to contradict the apparent spirochæticidal properties of the insoluble preparations.

Certain rabbits were injected subcutaneously under the skin of the ear with an insoluble bismuth derivative (the double iodide of bismuth and quinine). Four weeks later they received scrotal inoculations of a syphilitic virus. No lesions were produced so long as the bismuth was left in situ, but if the deposit of bismuth was removed by cutting the ear, infection spread and spirochætal chancres appeared in the region of the scrotum. Further, the popliteal lymph glands of the rabbits which had shown no syphilitic symptoms, when inoculated into another series of animals, produced undoubted syphilitic infections. Bismuth had thus not prevented the penetration of the virus into the organism and its location in the popliteal ganglia.

We cannot agree that these results warrant the conclusions which Kolle and Anwyl-Davies have drawn from them, and we are convinced for the following reasons that they do not.

The Spirochæticidal Efficacy of Bismuth.

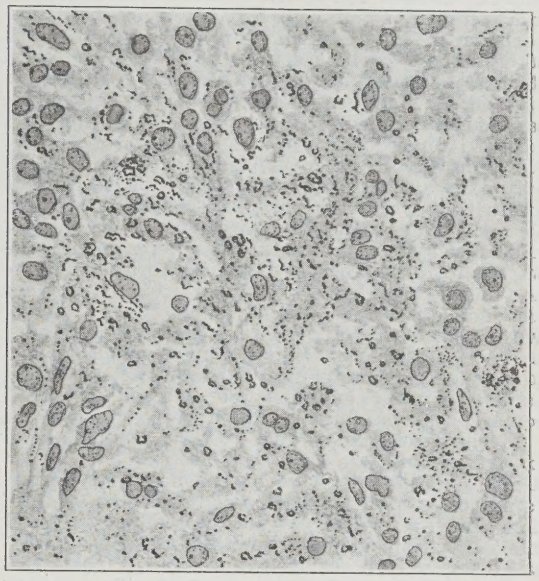
If the evolution of the spirochætes, in the syphilitic lesions of experimental animals which have been given an effective bismuth treatment, be followed day by day, a progressive alteration of the parasite can be readily seen. The spirochætes little by little lose the regularity of their undulations, become rod-like, show moniloform swellings, break up, and become transformed into granules and tiny grains, showing an affinity for silver. Finally, these involuted forms of the parasite are absorbed by the elements of the reticulo-endothelial system, the fibroblasts, and macrophages. This process, which takes place in the course of a few days, coincides with the immobilisation and disappearance of the spirochætes as shown by ultra-microscopic examination. Simultaneously the scrotal lesions diminish in size and are finally completely cured, in a period of time which varies according to the dose, the nature of the bismuth preparation administered and the severity of the lesion. Admittedly spirochætes which can be stained with

silver are still found, more or less distorted, for a considerable time after injection, but they are quite non-virulent when tested by inoculation of the residual nodule into normal animals. On the other hand, the persistence of these non-virulent involuted forms can also be demonstrated in animals treated with novarsenobenzol and certain arseno-bismuth derivatives.[3 4] There can be no doubt, therefore, that bismuth brings about in vivo an involution of the spirochætes which finally results in their destruction (as can readily be seen under the microscope) and a complete loss of virulence. (Figs. 1 and 2.)

FIG. 1.

Section of syphilitic chancre of a rabbit before injection of bismuth.

FIG. 2.



Same as Fig. 1, 3 days after injection of bismuth.

Fournier and Schwartz[5] published in 1926 the report of a series of experiments from which they concluded:—

(1) That insoluble bismuth compounds, metallic bismuth,[6] and certain lipoid-soluble compounds, injected intramuscularly into a rabbit, quite definitely protect the animal against experimental syphilitic infection.

(2) That this protection, as shown by several successive inoculations, varies from three months (for soluble salts) to six months (for insoluble derivatives). In general the duration of the protection has appeared to be proportional to the quantity of bismuth injected, and to depend, to some extent, on the nature of the compound employed, the insoluble derivatives and the metal itself appearing to be most effective.

(3) The animals have, finally, contracted syphilis, which certainly shows that they remained for months protected from possible infection.

This last point is very important. It has been shown that a syphilitic infection, even although it remains dormant, often confers a definite prophylaxis against a trial inoculation carried out with the same strain of virus. If, therefore, in the experiments of Fournier and Schwartz, there had been any such dormant infection; if, in other words, the bismuth had simply prevented the development of visible lesions without exerting any deep-seated sterilising action, it would have been impossible successfully to reinfect these animals at any time. It follows, therefore, that bismuth exerts a real prophylactic action, by destroying the spirochætes at the very site of injection.

Quite recently C. Levaditi and Y. Manin[7] have published similar experiments, which may be summarised as follows:—

(1) In the first series of experiments, rabbits were injected intramuscularly with basic bismuth tartrate (Bi = 74·47 per cent.) in a dose of 0·056 g. Bi per kg. The animals were then infected by scrotal inoculation with Truffi's virus on the 8th, 57th, 111th, and 152nd day after administration of the product.

(2) In the second series, the rabbits were similarly injected with the metallic bismuth in glucose suspension (Bi = 87·5 per cent.) in a dose of 0·043 g. of Bi per kg. (a slightly lower dose than the preceding). These were similarly infected 5 and 73 days after the bismuth injection.

The results of inoculation having been duly noted, the animals were killed, in order to determine the bismuth content of the various organs (method of Girard and Fourneau).

Results.

First series. (Basic bismuth tartrate.) No animal contracted syphilis, in spite of the very considerable duration of the experiment (195 days). On the other hand, inoculation into normal rabbits of the popliteal lymph glands showed their complete sterility, which, taken in conjunction with the fact that the Meinicke turbidity reaction was negative, demonstrated the absence of any dormant infection and the real prophylactic action exerted by bismuth in this series of experiments.

Second series. (Metallic bismuth.) The animals were resistant to the first inoculation carried out on the fifth day after the first injection, but seven of the nine animals (77 per cent.) developed syphilis after reinfection 73 days subsequent to the injection. Further, the popliteal lymph glands of one of these animals which had not developed any scrotal lesion after the first spirochætal infection were found to be virulent.

It follows that bismuth administered in the form of an insoluble compound (basic tartrate) exerts a prophylactic action which is still effective 152 days after the injection, while metallic bismuth, in a similar dose, produces a prophylactic condition which disappears toward the end of the seventy-third day. The superiority of the insoluble compounds over metallic bismuth is, therefore, incontestable.*

In order to determine the mechanism of this protective action, we have compared the efficacy and duration of the protection with the bismuth content of the various organs, and in particular with that of the kidney. (Tissue metallic potential.)

The recorded figures show (1) that the absolute and prolonged protection afforded by basic bismuth tartrate corresponds to a high tissue content of bismuth, apparent at the beginning, and persisting to the end

* Further experiments have shown that bismuth in a soluble form (solubilised bismuth quinine iodide) affords, when injected, a prophylactic effect much inferior to that of metallic bismuth; the duration of the protection does not extend for more than 30 days.

of the experiment; (2) that in animals which have received metallic bismuth (the initial prophylactic action of which is completely exhausted by the seventy-third day) this bismuth content is always lower.

In other words, the kidney tissue metallic potential of rabbits injected with basic bismuth tartrate is shown to be decidedly superior to that of animals which have received metallic bismuth.

We conclude from these experiments that the preventive action of bismuth in experimental syphilis of the rabbit is, dose for dose, more complete and lasting when administered in the form of an insoluble derivative, such as the basic tartrate, than as metallic bismuth. This is due to the fact that the conversion into a bismuth protein complex, and consequently the absorption of the bismuth, is more complete in the first case than in the second; this is shown by the fact that the renal metallic potential is higher in the first case at whatever time its value is determined. The insoluble bismuth compounds appear more readily to undergo in situ the changes requisite for their assimilation, whereas bismuth itself, which is partly fixed and isolated by a process of encystment, appears to be absorbed more and more slowly the longer the time after the injection. Like those of L. Fournier and A. Schwartz, these experiments show that bismuth administered in the form of one or other of its insoluble compounds is capable of conferring effective and lasting protection, provided, however, that the quantities injected are sufficient and that the tissue metallic potential reaches a level below which no therapeutic or prophylactic action is possible. Further examination of syphilitic grafts inoculated into animals thus protected shows that up to the twelfth day these grafts are completely non-virulent and free from spirochætes.

Other experiments have established that bismuth acts not only on the spirochætes present in syphilitic lesions, but even on the virus which is present in the popliteal lymph glands of rabbits with syphilitic scrotal lesions. It is well known [8 9 10] that these glands are almost constantly virulent. To determine whether they remain so after the administration of sufficient doses of an effective antisyphilitic, we carried out nine experiments[11] in collaboration with MM. S. Nicolau and V. Sanchis-Bayarri.

Rabbits with extensive scrotal chancres were treated either with the basic tartrate of bismuth (0·1 g. per kg. in 5 cases) or with a soluble form of the basic bismuth salt of stovarsol (0·2 g. per kg. in 2 cases), and as a control with novarsenobenzol (0·05 g. per kg. in 2 cases). The popliteal lymph glands were dissected out at various intervals afterwards, and grafted into the scrota of normal rabbits. Of 24 inoculations of the glands and several grafts of the chancre, 2 only gave positive results, in 1 case with a chancre excised 5 days after the injection of the bismuth compound and in the other with a gland examined 18 days after the commencement of treatment. It is interesting to note that bistovol, even when administered orally, sterilised the glands.[12] We concluded that in the very great majority of cases the popliteal glands of animals with syphilitic chancres, which have received effective treatment with a bismuth or bismuth-arsenic compound, are deprived of their virulence.

It follows that bismuth, either alone or in combination with arsenic, acts not only on the spirochætes and the observable specific lesions, but also on the virus seated in the deep tissues, particularly in the lymphatic glands. Its curative action is consequently far-reaching, since to all appearances it brings about in the rabbit a complete sterilisation of the organism.

Absorption and Elimination.

On this question, which has been studied by different experimental methods by many authorities,[13 14 15 16] we entirely agree with Dr. Anwyl-Davies. The conditions of absorption and the toxic effects on the kidney show that the insoluble salts of bismuth are better tolerated than the soluble derivatives—e.g., sodium potassium bismuth tartrate. This was established by the earliest researches of Levaditi and Sazerac. The experiments of C. S. Leonard and O'Brien,[17] to which Anwyl-Davies refers, find their true interpretation in the protective action of insoluble compounds of bismuth and of the metal itself. If the organism tolerates greater quantities of bismuth in the form of metal it is because the absorption of the metal is incomplete. Local reaction indicating a histochemical process resulting in the production of active bismuth protein complexes (cf. bismoxyl), is slower and less complete with bismuth metal than with insoluble bismuth derivatives (basic bismuth tartrate or bismuth oxide or hydroxide). A process of encystment isolates the metallic bismuth, and results in a definitely lower tissue metallic potential and a prophylactic action which is irregular, incomplete, and transient.

Therapeutic Results.

The therapeutic results of every new antisyphilitic remedy must be considered from the following points of view: (1) the action on the spirochætes; (2) the influence on the specific lesions at any stage of the disease; (3) the influence on the serological reactions —e.g., Wassermann, Bauer Hecht, or Meinicke and Vernes' turbidity reaction. Dr. Anwyl-Davies examines the effect of bismuth therapy on these different factors, and compares them with those obtained with the arsenobenzols or with mercury.

(1) So far as the action on the spirochætes is concerned, Dr. Anwyl-Davies confirms all that we had already established by our earliest experiments, which have since been verified by all those who have studied this question of bismuth therapy in a sufficient number of cases.[18] Bismuth frequently brings about the disappearance of the spirochætes after the first injection, occasionally only after the second injection. Very rarely a third injection may be required. Naturally the time depends very much upon the patient, the dose, and the nature of the preparation. Dr. Anwyl-Davies lays stress upon the fact that the spirochæticidal action of bismuth is slower than that of the arsenobenzols; this is true for insoluble but not for soluble bismuth preparations. We have found that the rational employment of a soluble preparation of the double iodide of bismuth and quinine (solubyl) causes the spirochætes to disappear as rapidly as does novarsenobenzol injected intravenously. With the insoluble derivative the slight delay in the spirochætolysis is due to the tissue reaction necessary for the formation of the active bismuth-protein complex (bismoxyl). This slight delay can, however, scarcely be considered a serious drawback to the therapeutic efficiency of bismuth. This criticism would only carry weight if one were considering exclusively the prophylactic action of bismuth in relation to that of arsenic. A delay of 24–28 hours could not possibly permit the syphilis to progress so far that bismuth treatment should be given up. What is equally, if not more, important is the appearance of relapses in spite of treatment. These relapses, in the opinion of all observers, are much more frequent with the arsenical compounds than with bismuth if the latter is suitably administered. In our opinion, the relative slowness of the spirochætolysis by bismuth is largely offset by the far-reaching and lasting effect of the drug and by the rarity of relapses.

Since 1921, when, in collaboration with Sazerac,[6] we introduced bismuth into the treatment of syphilis, one of us has almost completely abandoned the use of the arsenobenzols and used bismuth only, even for vigorous treatment. Generally speaking, soluble derivatives are first employed to hasten the destruction of the spirochætes; insoluble preparations are given at the same time to ensure a thorough and lasting action. In certain cases arsenic is used as an adjuvant in forms that can be administered orally, such as stovarsol. We have never had any fault to find with this mode of treatment. If in the course of our vast experience, including at least 4000 cases of syphilis in all stages, we had perceived the slightest inferiority in our method to that employed in other hospitals, either in France or abroad, we should not have hesitated to abandon or to modify it.

(2) We have found bismuth equally effective in curing the specific lesions. On this point we are at any rate partly in agreement with Dr. Anwyl-Davies, since he himself acknowledges the rapid effect of bismuth on the mucous manifestations of secondary syphilis and on the tertiary lesions. This agreement, however, ceases when he makes a distinction between specific lesions which are amenable to bismuth treatment and those which are not. Syphilis in all its forms is amenable to cure by bismuth, from the outset (vigorous treatment) to the tertiary and late nervous stages. This is not to say that treatment by arsenicals should be abandoned, for splendid results are obtained by the simultaneous exhibition of bismuth and arsenic. Our observations show, however, that perfectly satisfactory results can be obtained without the intravenous injection of any of the arsenobenzols.

(3) As we have said many times during the last few years, bismuth acts on the Wassermann and similar reactions quite as well as, and sometimes better than, arsenic. We have put on record numerous examples of positive reactions irreducible by arsenic (relapses after treatment by the arsenobenzols) which have yielded to treatment with bismuth.

Dr. Anwyl-Davies gives figures from St. Thomas's Hospital which seem at first sight to prove that mercury has a better effect than bismuth on the serological reactions. The series he deals with was a mixed one, consisting of primary cases, some with positive and some with negative reactions, and of secondary cases with a roseolar or papular rash. 240 patients were given 5 g. "914" and 8 g. mercury; 185 patients were given 5 g. "914" and an average of 3·6 g. bismuth. The results on the Wassermann reaction were: 81·7 per cent. negative in the first group, and 77·3 per cent. in the second. Dr. Anwyl-Davies holds that this is a point in favour of the superiority of mercury. Needless to say, we cannot agree with him. The 4·4-per cent. difference between the two results is within the margin of individual variation. Syphilitic infection varies even more in the human subject than it does in animals. Moreover, the comparison between mercury and bismuth is vitiated by their employment in conjunction with arsenic.

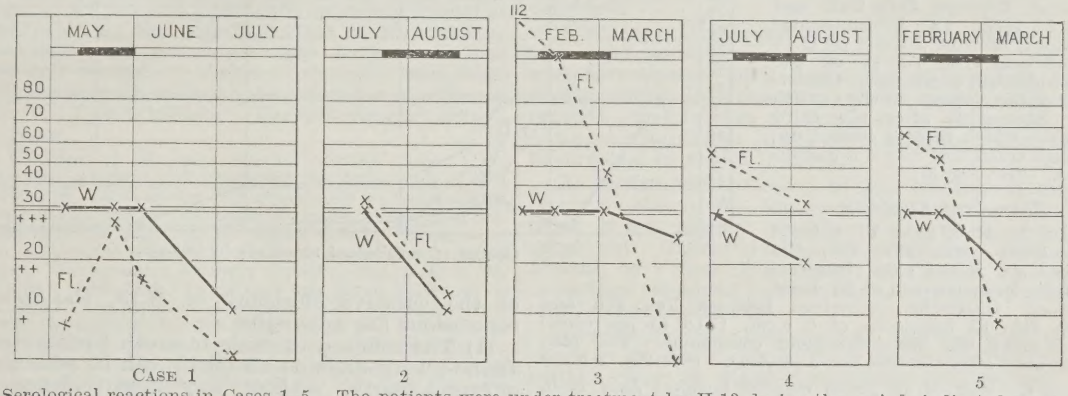
Bismuth-Arsenic Preparations: Bi-Stovarsol.

Bistovol (basic bismuth stovarsol) is a 10 per cent. suspension in oil of 41 per cent. bismuth and 15 per cent. arsenic. It was prepared and studied experimentally by Levaditi in 1924,[19] and tried on the human subject by Fournier and Schwartz.[20] Fournier used it for the treatment of 20 syphilitic patients with chancres or secondary symptoms, and records the following results:—

The spirochætes disappeared (chancre ten cases, mucous patches or erosive lesions eight cases) in from 24 to 48 hours after the first injection. In two cases only was a second injection required. The primary or secondary lesions cicatrised rapidly as with the best bismuth preparations, and adenitis, rash, papular eruptions, and general symptoms disappeared with equal celerity. The marked diminution or complete disappearance of the complement-fixation reaction showed the thoroughness of the therapeutic effect.

These experiments were all carried out with the basic bismuth stovarsol prepared from sodium potassium bismuth tartrate, and the sodium salt of p-hydroxy-acetyl-amino-phenyl-arsinic acid. Since then the preparation has been manufactured, particularly in England, under the name of bistovol. Dr. Anwyl-Davies reports that he used bistovol at St. Thomas's Hospital, but was unable to confirm our clinical results. He says that the injections were very painful, and that motile spirochætes were found six or even seven days after the first dose. "When it was found," he says, "that *S. pallida* were present seven days after a single dose of 0·3 g., and the negative Wassermann reaction had become strongly positive (++) during the same time, stronger doses were injected at shorter intervals. In two cases 0·6 g. was injected in three days, but the spirochætes were found alive five days after the initial dose, and the Wassermann reaction was positive (++). In two other cases 0·75 and 0·9 were given, but the spirochætes were active on the fourth and fifth days respectively."

FIG. 3.



Serological reactions in Cases 1–5. The patients were under treatment by H.13 during the periods indicated by the thick black lines at the top of the chart. W = Wassermann reaction. Fl = Flocculation.

We cannot explain the difference between our results and those of Dr. Anwyl-Davies. In most of our patients the spirochætes disappeared within 24 or 48 hours after the first injection, and many other workers agree with us that the bistovol exerts a definite effect, both on the clinical symptoms and on the serological findings, as soon as the first series of injections is completed.

Since our early experiments were published it has been found possible to produce a perfectly clear and stable solution of bistovol† for use in strengths equivalent to 2 or 10 per cent. of bistovol. This solution is known as H.13. One of us[21] has studied the action of this product on syphilitic rabbits with chancres experimentally produced by the inoculation of Truffi's virus, or with preputial lesions due to *S. cuniculi* (rabbit spirochætosis). Its therapeutic efficacy is remarkable. Injected intramuscularly, H.13 shows a chemotherapeutic index of 1:35. It acts not only on the spirochætes of the external lesions, but also on the syphilitic virus in the popliteal glands. Lesions cicatrise in a few days, although the dose of bismuth is not more than 0·00082 g., and that of arsenic 0·0003 g. per kg.

Therapeutic trials on man have been carried out in the Hopital Cochin.

Primary Syphilis.

CASE 1.—A man 22 years of age entered hospital on May 9th, 1927. Chancre of prepuce. Bilateral inguinal

† The authors are indebted to Messrs. May and Baker, Ltd., London, for supplies of the various bismuth-arsenical preparations employed in the course of this investigation.

adenitis. Spirochætes present; Bauer Hecht and Wassermann reactions strongly positive; flocculation, 6. Received, intramuscularly, from May 10th to June 1st, 10 injections of 2 c.cm. H.13 (10 per cent.), being in all 2 g. of bistovol. Spirochætes disappeared the day after the first injection, cicatrisation of the chancre commenced on the third day, and cure was rapid. On July 8th persistence of the polyglandular inguinal adenitis was noted. The changes in the serological reactions are shown in Fig. 3.

CASE 2.—Man, aged 25 years, entered hospital July 19th, 1927. Indurated chancre of the prepuce dating from 15 days previously. Bilateral inguinal adenitis. Bauer Hecht and Wassermann reactions markedly positive. Calmette-Massol reaction positive. Flocculation, 38. It was impossible to demonstrate spirochætes in the chancre fluid. Received, between July 20th and August 18th, 12 intramuscular injections, each of 5 c.cm. of H.13 (2 per cent.) or 1·2 g. of the arseno-bismuth compound. Cicatrisation of the chancre on the twelfth day. Stomatitis after the third injection, which rapidly cleared up, although treatment was not discontinued. (See Fig. 3.)

Secondary Syphilis.

CASE 3.—Boy, aged 17, entered hospital Feb. 15th, 1927. Preputial chancre six weeks old. Bilateral adenitis. Roseolar rash of 10 days' duration. Headache. Received between Feb. 8th and March 4th, 12 injections of 5 c.cm. H.13 (2 per cent.) or 1·2 g. of the bismuth-arsenic compound. The rash disappeared after the first few injections. (See Fig. 3.)

CASE 4.—Man of 36 years, entered hospital July 12th, 1927. Mucous plaques on the prepuce, anus, and scrotum. Syphilitic chancre a year ago. Spirochætes present. All the serological reactions strongly positive. Flocculation, 58. Received, between July 8th and August 5th, 12 injections of 3 c.cm. H.13 (2 per cent.) or 0·72 g. of the bismuth-arsenic compound in all. The spirochætes disappeared the third day after the first injection. The lesions were rapidly cicatrised. Mild stomatitis July 25th. (See Fig. 3.)

CASE 5.—Man, aged 21 years, entered hospital Feb. 3rd, 1927. Slight chancre in November, 1926; cicatrised in 8–10 days. In January laryngitis, alopecia, roseolar rash; on entry mucous plaques and bilateral inguinal adenitis. All the serum reactions strongly positive. Flocculation, 64. Received from Feb. 7th to March 7th, 12 injections of 5 c.cm. H.13 (2 per cent.) = 1·2 g. of the compound. The lesions cicatrised in a few days. (See Fig. 3.)

CASE 6.—Man, aged 30 years, entered hospital Sept. 29th, 1926. Cicatrised chancre of the prepuce. Bilateral inguinal buboes. Roseolar eruption. Headache; periostitis. All serum reactions strongly positive. Flocculation, 95. Received, from Sept. 29th to Oct. 25th, a first series of 12 injections of H.13 (10 per cent.); then from Nov. 20th–26th, six further injections = altogether 5·4 g. of the compound. After the fourth injection the rash became paler and disappeared; the patch of periostitis progressively decreased. The serological reactions became negative in January.

In some cases we have combined the treatment by injections of H.13 with a course of stovarsol, and of the bismuth salt of stovarsol per os. The following case affords an example:—

CASE 7.—Man, aged 29 years. Entered hospital Jan. 28th, 1927. Chancre of the frenum had commenced five months previously. Inguinal adenitis, all the serological reactions strongly positive. Flocculation, 33. Received, July 29th and 31st, 4 c.cm. H.13 (2 per cent.), then from Feb. 2nd to 28th, 5 c.cm. of the same product daily. From March 27th to April 6th, eight tablets of bistovol (0·25 g. per tablet) per day.

Although these patients have not been followed up long enough to enable us to make a definite estimate of the curative efficiency of H.13, the following conclusions are admissible:—

(1) The solution of basic bismuth hydroxy-acetyl-amino-phenyl-arsinic acid (H.13) can be administered intramuscularly, without any inconvenience other than a certain amount of pain (which varies with the patient and the dose injected) after the injection, and a negligible stomatitis. (2) That H.13 has curative properties is shown not only by its very rapid effect on the spirochætes and on the specific primary and secondary lesions, but still more by its effect on the serological reactions, which have been rendered negative or nearly so by the administration of an amount equivalent to 0·72 g. to 2 g. over a single series of 12 injections.

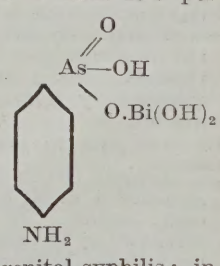
Bismuth Arsanilate and Bismuth Tryparsamide.

Other bismuth derivatives of similar arsenical compounds are bismuth arsanilate and bismuth tryparsamide.‡ Bismuth arsanilate was first prepared by J. O. Shircore, Director of Medical and Sanitary Services, Tanganyika. It has the formula here shown, and contains 45·5 per cent. of bismuth and 16·3 per cent. of arsenic. Shircore reported in a letter to THE LANCET [21] the observations of J. G. McNaughten concerning 1158 cases of yaws and 538 cases of syphilis treated with this preparation. The severest lesions of yaws were cured in a few days, so that it was unnecessary to give more than two injections. The author had only treated cases of tertiary and congenital syphilis; in 75 per cent. six injections were sufficient to bring about a complete healing of the lesions. Only 10 of the 1696 cases treated showed any signs of stomatitis. Shircore concludes that bismuth alone



‡ This product is at present the subject of investigation, the results of which will be reported later.

is quite effective in syphilis, but that the bismuth-arsenic compound is much better; the mild character and low percentage incidence of the stomatitis are distinct advantages in its favour.

We have also experimented with bismuth arsanilate, both in animals and in man.[12] In intramuscular doses of 0·1 to 0·05 g. per kg. it brings about the rapid destruction of spirochætes and prompt cicatrisation of lesions. Our impression is that it is suitable for intramuscular injection, which is quite painless and perfectly well tolerated, and that it compares with the best preparations of insoluble bismuth derivatives.

Oral Administration of Bismuth-stovarsol.

Analyses undertaken in collaboration with Mlle. Y. Manin, according to the very sensitive method described by Girard and Fourneau, have demonstrated the absorption by the digestive tract of both arsenic and bismuth, and about a dozen patients in the primary and secondary stages of syphilis have been treated entirely with bismuth-stovarsol per os, either in solution (H.13) or in tablets. The following are details of the cases.

CASE 8.—Man of 59 years entered hospital Sept. 11th, 1926, showing a bright red triangular preputial rash of two fingers-breadth, surrounding the glans with an œdematous pad. Syphilitic rash on the arms and chest three days old. Commencement of infection five weeks before. Absence of adenitis. Spirochætes present in the surface of the preputial ulceration; Wassermann strongly positive; flocculation, 54.

From Sept. 11th–18th the patient was given daily per os 20 c.cm. H.13 (2 g. bismuth-stovarsol). On the second day, Sept. 13th, the spirochætes disappeared and the rash cleared up. On Sept. 16th the lesion had assumed the appearance of muscle tissue; it had diminished in width, and the edges showed signs of cicatrisation. From Sept. 19th–25th, a second series of doses of H.13 (20 c.cm. daily). On Sept. 23rd, 12 days after commencement of treatment, the lesion had diminished by one-half and cicatrisation progressed from day to day. On Sept. 27th the serological reactions were as follows: Bauer Hecht positive, Wassermann weakly positive; flocculation, 38 (in place of 54). 20 c.cm. were given daily from Oct. 6th–27th; 25 c.cm. daily from Oct. 22nd–28th; 10 c.cm. daily from Nov. 15th–19th; 10 c.cm. daily from Nov. 20th–27th; 20 c.cm. daily from Dec. 8th–19th. From Jan. 8th–15th two tablets of 0·5 g. daily. The patient, therefore, received altogether, in the space of 126 days, 119 g. of the bismuth-arsenic derivative without any untoward effects. The course of the serological reactions is shown in Fig. 4.

CASE 9.—Woman, aged 25 years. Entered hospital Dec. 2nd, 1926. Syphilitic rash. Reactions: Bauer Hecht, Wassermann, and Calmette–Massol, all strongly positive; flocculation, 112. Received one injection of H.13 (3 c.cm. 10 per cent.) which was badly tolerated, followed from Dec. 2nd–6th by a daily dose of 5 and 10 c.cm. H.13 by mouth. The subsequent treatment was as follows:—

Course.

2nd ..	Dec. 10th–22nd	}	15 c.cm. H.13 daily.
3rd ..	,, 25th–Jan. 3rd		
4th ..	Jan. 10th–21st	}	0·75 g. (3 tablets 0·25 g.) daily.
5th ..	,, 31st–Feb. 9th		

The patient therefore received, over a period of 50 days, 51 g. of bismuth-stovarsol by mouth. The serological reactions are shown in Fig. 5.

CASE 10.—Woman of 30 years. Came into hospital Jan. 7th, 1927. Infected mucous plaques and vegetative ulceration on the thighs and labia majora dating from a month previously. Rash. Serological reactions strongly positive. Flocculation, 70. The treatment was as follows:—

Course.

1st ..	Jan. 7th–19th	}	12 doses (in tablets) of 0·75 g.
2nd ..	,, 24th–Feb. 4th		
3rd ..	Feb. 10th–28th		

On Jan. 19th, 12 days after commencing treatment, the rash had completely disappeared and cicatrisation of the mucous plaques had commenced. The patient, who was completely cured, received in a period of 52 days 26 g. of bismuth-stovarsol.

CASE 11.—Boy, aged 15 years. Entered hospital Feb. 14th, 1927. Phimosis and subpreputial induration commenced six weeks before. Inguinal adenitis; Wassermann negative. Feb. 21st, Wassermann weakly positive. March 2nd, all serological reactions strongly positive. Flocculation, 22. The treatment was as follows:—

Course.

1st ..	March 4th–14th	}	2 g. of the compound daily.
2nd ..	,, 20th–28th		
3rd ..	April 11th–21st		
4th ..	May 11th–18th		

On March 17th, phimosis disappeared, chancre cicatrised (13 days after commencement of treatment). The patient received in the course of 75 days 78 g. of bismuth-stovarsol.

Conclusions.

Our clinical experience as a whole, and these observations in particular, lead us to the following conclusions:—

(1) Bismuth-stovarsol administered by mouth, whether in solution or in the solid form, is perfectly well tolerated in doses of 2 g. daily for a period of 8–11 days. Even with this very considerable dosage, corresponding to 0·82 g. of Bi. and 0·3 g. As. per day, we have never observed any digestive or other disturbance worthy of note, with the exception of two cases, in which a generalised erythema appeared but quickly subsided.

(2) Cases of primary and secondary syphilis, in which the serological reactions were strongly positive and spirochætes were demonstrably present, have shown rapid disappearance of the spirochætes and prompt cicatrisation of the lesions. The rash has disappeared in from 10–12 days, and the lesions have been cured in about 13 days.

(3) Under the influence of the treatment, exclusively by the mouth, the serological reactions become more or less rapidly negative whatever the reaction employed (Bauer-Hecht, Wassermann, Calmette-Massol, or Vernes' flocculation reaction). In certain cases they remained negative for a long period without any further treatment.

Admittedly our cases are few, and the time is too short to permit us to judge definitely of the therapeutic value of bismuth-stovarsol administered by mouth. Nevertbeless, it is not going too far to suggest, from the actual clinical records, the usefulness of this method of treatment in all syphilitic cases where treatment by injection is contra-indicated, or where it is necessary to employ a method of treatment which is convenient and well tolerated by the patient.

We purposely leave out any comparison of the therapeutic value of bismuth as against mercury. Dr. Anwyl-Davies is the only author, among the numerous workers who have considered the question, to cast any doubt on the superiority of bismuth over mercury. We will leave it to him to support his opinion by clinical and experimental evidence. In the meanwhile we hold to our own view—viz., that mercury by reason of its toxicity, the severity of the mucous and renal lesions which it provokes, the mediocrity of its therapeutic value, and the difficulties and uncertainty attaching to its employment, is definitely of less value than bismuth.

TRANSCONDYLAR FRACTURES OF THE HUMERUS IN CHILDREN.

By F. D. SANER, M.B. Camb., F.R.C.S. Eng.,
SURGEON, AND SURGEON IN CHARGE OF THE FRACTURE DEPARTMENT, ROYAL NORTHERN HOSPITAL LONDON.

FRACTURES of the lower end of the humerus in children may be grouped under three headings as follows:—

(1) *Supracondylar* fractures in which the line of fracture is through the lower end of the shaft of the humerus, above the fossæ and the attachment of the capsule of the elbow-joint, unless of the T-shaped variety.

(2) *Transcondylar* fractures, in which the line of fracture is accurately at the level of the condyles or immediately above or below them, traverses the fossæ, and is in part, at any rate, within the capsule of the joint. This fracture has frequently been described under Group I. or as a fracture-separation of the lower humeral epiphysis.

(3) *Condylar* fractures, in which a small fragment including the condyle is separated from the inner or outer aspect of the bone, the line of fracture being oblique or vertical in direction and involving as a rule the epiphysial line.

Although the general principles governing the treatment of the three groups are essentially the same, it is the transcondylar fracture to which reference is now made, since besides being very common, is of importance as it may present special difficulties in both the immediate and the after-treatment.

Characteristics of the Fracture.

The line of fracture is usually somewhat crescentic with the concavity upwards, and passes transversely between the condyles through or near the centre of the olecranon fossa, while the fractured surfaces are slightly oblique. There is therefore a long upper fragment of diaphysis and a very short lower one consisting of a small fragment of diaphysis and the epiphysis, which are usually of about equal depth; it is rare for the epiphysial line itself to be involved. The fracture may be incomplete or complete without displacement, but if it is complete displacement is generally marked and typical. The long upper fragment is thrust forwards and in the severe case may come to lie under the skin on the anterior aspect of the elbow or may penetrate it. The small lower fragment consisting of the fragment of diaphysis and the epiphysis is tilted forwards and together with the whole forearm is carried backwards, limited to some extent by the triceps tendon. The main displacement is of the long upper fragment which as just stated is usually displaced forwards, occasionally laterally and rarely backwards. The capsule of the elbow-joint is torn and the periosteum on the posterior aspect of the humerus is extensively stripped up, and from these, as well as from the network of vessels surrounding the lower end of the bone, there is usually considerable effusion of blood round the site of fracture. This effusion, together with the displacement of the bone fragments, creates a tension which may interfere with the circulation in the main vessels of the limb. In one case in my own experience the hand became gangrenous as the result of tension from the injury alone; in another case the same thing happened as a result of the arm being fixed with the elbow flexed in the presence of much tension; while on several occasions the circulation of the hand has been interfered with temporarily as an immediate result of the injury.

The deformity of the elbow is, as a rule, obvious, the contour of the region being entirely altered while all bony landmarks are obliterated by the swelling. Manipulation of the elbow or arm for the purpose of diagnosis is to be avoided, since apart from causing much pain and perhaps further damage, an accurate diagnosis of any injury in this region is impossible without X rays. Radiograms in two planes should be taken as soon as possible, and though under certain conditions this may cause delay, apart from temporary immobilisation it is unwise to attempt treatment until these have been obtained, and it is, too, a great help to have control radiograms of the sound elbow for comparison.

Treatment.

If when the case is first seen there are any signs of interference with the circulation as shown by a difference in colour or temperature of the fingers or hand, or any alteration in the volume of the pulses, or if the effusion round the elbow is so severe as to suggest that such interference might occur, any manipulation of the arm is, in my opinion, contra-indicated. It may be argued that restoration of alignment of the bone fragments will help to lessen the tension and this is probably so; but it is in such cases that the reduction is difficult owing to the effusion and tension, and manipulation may have to be prolonged and perhaps forceful so that definite risks are run of damaging further an already embarrassed circulation.

When the case is first seen, therefore, every care should be taken to discover any sign of interference with the circulation, and the same care should be exercised afterwards when the splint or bandage, as the case may be, has been applied. Apart from a certain degree of aching, a fractured limb after reduction and immobilisation should be comfortable; pain may be taken as an indication of pressure either from incomplete reduction or faulty splinting, and should always demand attention.

In cases, therefore, with severe effusion and signs of interference with the circulation, the arm should be supported temporarily on a wide internal angular splint with the hand and forearm covered while the gentlest stroking movements are applied to the elbow region to assist the absorption of effused products. As a rule a gradual improvement will take place in the course of two or three hours, but if at the end of this time there is no improvement or the contrary, the condition is to be regarded as an emergency, demanding operative measures to evacuate the effused blood and to restore alignment of the fragments. On the other hand, if the circulation returns to normal, and as a rule it does, it is unwise to carry out any manipulation for at least 24 hours. By this time the presence of much blood-clot will prejudice or perhaps prevent reduction, and if reduction cannot be obtained, provided the condition of the skin is satisfactory, an open operation should be performed without undue delay. In cases therefore with effusion of blood of marked severity operative measures, either immediate or when suitable, provide, in my opinion, the safest means of avoiding danger and dealing with the deformity.

In the ordinary case with displacement an attempt at reduction must be made immediately under full anæsthesia. The upper arm of the patient is held firmly while the wrist is grasped and steady traction applied with the forearm extended as far as is possible; still maintaining traction, the forearm is slowly flexed. The whole movement should be firm and slow as any degree of force is liable to cause damage. Where there is lateral displacement the same movements are carried out and direct pressure applied over the lower end of the upper fragment. My impression is that reduction is usually possible in the early stages; in the others it fails chiefly owing to the presence of blood-clot. A delay of a few days to allow absorption of the effusion before attempting reduction defeats its own object, for the blood when organised causes a still more solid resistance, while in these cases callus is formed with considerable rapidity. If, therefore, a genuine attempt at non-operative reduction has failed, a second trial is unlikely to be any more successful and an open operation should be advised, since an uncorrected displacement results in permanent deformity and diminished function.

The best approach to these fractures is by a midline incision on the posterior aspect of the arm. The skin, subcutaneous tissue, aponeurosis, and muscle of the triceps is divided and the blood-clot cleared from the site of injury. The site of fracture even after a few days may be completely obscured by a thin layer of callus, which requires removal. The forearm is extended as far as possible and a light lever is inserted

between the two fragments, and while the forearm is slowly flexed the long upper fragment is levered backwards. Several attempts may be necessary to obtain satisfactory reduction and care must be taken to avoid injury to the small lower fragment. When reduction has been obtained, no fixative metal or otherwise should be introduced. This small operation which in principle is simple, sometimes presents much difficulty in accomplishment.

Whether reduction has been obtained by operative or non-operative means, there is a tendency for the displacement to recur, and the best means of avoiding this is by a position of flexion at the elbow which creates traction on the lower humeral fragment and holds it together with the forearm in a forward position, and, with due care that there is no interference with the blood-supply, flexion is the position of choice for maintaining reduction. A common impression exists that flexion per se helps reduction, and on account of this there is rather an undue anxiety to obtain this position as soon as possible in all fractures in the elbow region. Flexion does not assist reduction, but is a useful means of creating traction on a small fragment at the lower end of the humerus, and helped by the action of the triceps tendon of maintaining a position obtained by manipulation; it should be used only if indicated as there is a certain element of danger especially in the presence of effusion, and it is unnecessary in fractures with no displacement, which need only be temporarily immobilised on any convenient splint. In any case flexion is unnecessary after two or three days or a week at the outside, when the arm should be released to a right angle supported by a sling only and voluntary movements of the elbow encouraged. There is no fear of slipping of the fragments after three to four days provided accurate alignment has been restored and *voluntary movements* only are employed, and this remark applies to many transverse fractures of the limb bones, if reduction with impaction has been obtained.

Formation of Callus.

In the natural course of repair callus, and owing to the vascularity of the part much callus, is quickly thrown out, and is increased in direct proportion to the degree of displacement left uncorrected. In any case, however, callus situated around and within the capsule of the joint and filling the grooves and fossæ at the lower end of the humerus mechanically obstructs movements both of flexion and extension at the elbow, and it is not until this has been partially absorbed, partially remodelled, and the capsule has been repaired and freed that full movement can be expected. This applies to any of the fractures in the region of the elbow-joint, and should be pointed out to parents in the beginning and insisted on as a natural course of repair, otherwise if at the end of many weeks movements are still limited anxiety is naturally expressed. One of the main objects of treatment, then, is to avoid excess of callus, and it can be limited to some extent at any rate by an accurate restoration of alignment and the employment afterwards of voluntary movements under supervision only. Malposition necessarily entails a greater output of callus and unequal repair of the capsule, and violence in the shape of passive movements, vigorous massage, or manipulation under an anæsthetic causes considerable irritation and effusion, and should be entirely avoided. Limitation of movements is not due to obstruction in the elbow-joint itself provided voluntary movements have been commenced early and are continued, but is mainly the result of an actual mechanical block by callus which may continue for weeks or months, but eventually disappears in most cases. There is the occasional case in which a mass of callus remains unabsorbed; in my experience this rarely happens in children, even in the presence of an uncorrected displacement; but in corresponding fractures in the adult it does sometimes occur in spite of a satisfactory alignment, while the difficult complication of ossification in the surrounding muscles is also occasionally met with.

Apart, then, from the employment and encouragement of voluntary movements under supervision from the third or fourth day onwards but little after-treatment is required. If there is much effusion in the early stages, effleurage should be employed; otherwise massage, as already mentioned, is rather to be avoided as a possible source of irritation which will cause further callus-formation.

CHRONIC GLAUCOMA.

THE IMPORTANCE OF EARLY DIAGNOSIS.

BY D. LEIGHTON DAVIES, M.D., M.S. LOND., F.R.C.S. ENG.,

OPHTHALMIC SURGEON, ROYAL INFIRMARY, CARDIFF.

ONE of the greatest and most terrible afflictions of middle or advancing years is the knowledge of impending and irrevocable blindness, and amongst the causes which lead to such blindness chronic or simple glaucoma is one of the commonest. As is well known, acute glaucoma stands in quite a different category from the chronic type, but nevertheless it is as frequently allowed to pass into blindness. The former may, and often is, mistaken for acute iritis, but the latter is often never recognised. I am convinced that if chronic glaucoma is taken in hand in an early stage there is every probability that vision can be permanently saved. It is one of the most insidious of diseases, and usually there are no well-defined symptoms or signs which can lead to its early detection by the general practitioner. Hence the danger; for the patients, either through want of observation or owing to an inherent gift of hope, do not complain of failing eyesight until quite late in the course of the disease.

Points in Diagnosis.

Chronic glaucoma occurs in both sexes almost equally. In 155 consecutive cases of the disease seen in private practice 79 were males and 76 females, and their ages ranged from 50–86, nine cases being below the age of 50 and the youngest being 26 years old. In a large percentage of cases the health is not good. The patient may have passed through some debilitating illness or some nervous strain. Indeed, the depressing effects of financial worries, the attempt to make ends meet, is as common a background as any, though prolonged and close attention on a sick relative, especially when ending in bereavement, is a very potent predisposing cause. In all such cases it behoves the practitioner to keep the idea of chronic glaucoma ever before his mind. The patient's eyes tire very easily after reading, and, thinking that it is only a question of procuring stronger reading-glasses, he goes to an optician and finds that he gets on much better with the new lenses. In a few months, however, or it may be only weeks, he again finds increasing difficulty in reading, especially at night. That I regard as a very dangerous and characteristic symptom in a person past middle age. Other patients state that the sight becomes misty and objects hazy. Sometimes, particularly during the period of obscuration, rainbow-coloured rings may be observed, but this is seldom mentioned by a patient. These transient periods of dimness of vision are probably associated with some slight rise of tension in the eye. After a longer or shorter interval the patient begins to observe definite failure of vision; small print presents increasing difficulty, especially at night, and eye weariness sets in quickly when attempting to read. All this while changes of deep significance have been taking place quite unconsciously. The visual field undergoes a gradual and progressive diminution in size, and the contraction may be of various types.

On examination the eye may seem to be perfectly healthy, with pupils equal and actively responsive to light. On the other hand, the cornea may show slight haziness, the anterior chamber be shallow, and

the pupil semi-dilated and reacting very sluggishly to light. In the latter type of case the tension of the eye is nearly always raised, sometimes markedly, whereas in those eyes which look normal it may be difficult to detect any rise in tension at all, though with the modern methods of tonometry it may be possible to detect a smaller rise of tension than could be detected with the finger. In all cases which have advanced beyond the earlier stages the ophthalmoscope will reveal some pallor of the optic nerve, with definite excavation of the nerve head. In the initial stages the optic disc may be hyperæmic rather than pale. The visual fields always become contracted, and their contraction may take on different types, such as defects of sector shape and greater involvement of the nasal portion, and this may be associated with almost normal visual acuity. Indeed, visual acuity is only seriously impaired at a comparatively late stage of the disease. The blind spot becomes definitely enlarged, and other blind spots (scotomata) may appear. The changes in the visual field are of greater significance in the prognosis than any other single symptom.

The pathogenesis of chronic glaucoma is not settled, but probably it is at any rate partially true to say that the direct cause is an intermittent or constant slight increase of tension in the eye, due perhaps to defective elimination of the ocular fluid.

The progress is almost invariably a steadily downward course; the visual fields become definitely more and more contracted, while central vision follows a little behind. At last the remaining central area of the field is contracted out and vision becomes hopelessly and permanently lost.

Treatment.

I am fully persuaded that, once the diagnosis is made, the earlier that operation is performed the better will be the result. No operation can materially improve sight that has been impaired by partial atrophy, but a suitable operation can, and does, retain sight that is present, and retain it permanently. It therefore follows that the better the sight at the time of the operation the better the permanent result, and the worse the sight the poorer the result. Yet, however bad sight may have become, operation may retain some ability to get about alone, and even that amount of vision is a very precious asset to an active person. The old method of iridectomy cannot be depended upon, and in the great majority of cases that have come under my observation iridectomy has been utterly useless. The modern method consists in producing a filtering cicatrix—i.e., a leaking channel—between the anterior chamber and the subconjunctival space, and is the only reliable method at present available. Several ways of attaining this result have been brought forward; personally, I have favoured that known as trephining and introduced by Lt.-Col. R. H. Elliot, and I make bold to say that the great majority of cases of chronic glaucoma can be saved by this operation.

On looking through my records of private cases I find that of 100 operations for chronic glaucoma the patient's sight has been retained in 91. Sometimes there has been some slight failure of vision without any sign of rise of tension or other pathological causes, but none of them have lost sight while under observation, which sometimes extends up to ten years and none under four months. The failures were: suppuration 24 hours after operation (a subacute case which became suddenly acute), 1 case; septic irido-cyclitis (one year after), 1 case; intraocular hæmorrhage after operation, 2 cases; inefficient operation (trephine hole becoming blocked), 2 cases; chronic irido-cyclitis starting after operation, 1 case; cataract soon after operation, 1 case; and gradual loss of sight due to progressive atrophy of the nerve, 1 case. In a few cases cataract developed some years after trephining, and in two or three of these subsequent extraction led to a return of ability to read easily.

I have operated upon ten cases where vision varied from counting fingers down to hand movements. Such vision is compatible with ability to get about in familiar surroundings. The result of operation has been satisfactory in that there has been a retention of such vision for periods varying from three months to four years after operation. On the other hand, I have operated upon a case in which vision was 6/6 in each eye, but the fields were definitely and rapidly contracting; in that partucular case it was essential to retain a high degree of visual acuity in order that the man should be able to carry on his work. The operation on both eyes arrested the progress of the disease and for eight years he was able to do very fine work. Cataract then began to affect vision, which is at present 6/36 in each eye.

Summary.

In the modern operation of trephining we have a method which in about 90 per cent. of cases will ensure a permanent cure for glaucoma; while it cannot restore sight lost, it can prevent further deterioration, and therefore it is always wise to operate as early as possible. At the same time, in a few cases it may be justifiable and wiser to wait, trusting to general hygiene and the wise ordering of the patient's method of living, together with the use of eserine. The large majority will ultimately lose sight unless operation is undertaken. The future may, and possibly will, bring an advance in our knowledge of the pathogenesis of the disease, and other methods may become available, but to-day to place our confidence on any other method than operation is to risk the loss of sight which might have been saved.

A FURTHER CASE OF MULTIPLE PANCREATIC CALCULI.

REMOVAL AND RECOVERY.

BY E. C. LINDSAY, C.B.E., M.B. LOND., F.R.C.S. ENG.,

SURGEON (WITH CHARGE OF OUT-PATIENTS), LONDON HOSPITAL; SURGEON, POPLAR HOSPITAL.

IN 1922 I recorded in THE LANCET [1] the operative removal of six calculi from the main duct of the pancreas by a direct anterior incision, followed by drainage of the duct for a few days. The uneventful recovery and continued good health of the patient after five years encourages the belief that the primary source of these stones, presumably infection, had been reduced, if not eliminated, by drainage.

As Moynihan points out, the recorded cases are so few as to leave the symptomatology of pancreatic calculi at any rate indefinite. A further case of this rare condition, therefore, in which previous pancreatic symptoms had occurred, and in which the diagnosis of calculi was confirmed by X rays, and later operation, may not be without interest.

I was asked by Prof. A. W. M. Ellis to see a case under his care in which suspicion of pancreatic calculi had arisen.

History.

The patient, a messenger, aged 43, gave the following history. In 1922, while walking along the street, he had a sudden severe pain in the abdomen under the costal margin. The pain increased in severity, radiating to the left shoulder, causing sweating but no vomiting. The pain subsided gradually, leaving him tender in the left hypochrondrium for two months. Attacks then recurred in the same area with the same radiation of pain, but less severe than the first, and associated with a gradual deterioration of his general health.

In December, 1924, he was admitted to hospital for investigation, when a rounded tender mass was discovered under the left costal margin, extending 4 in. below the costal margin towards the umbilicus. A differential blood count showed 15,000 leucocytes. Ten days after admission sudden severe abdominal pain occurred with vomiting and the abdomen became rigid. Laparotomy was performed, and the abdomen was full of blood-stained fluid resulting from the rupture of a collection of fluid in the lesser sac. Drainage was established, and the patient was discharged a few weeks afterwards.

Three months later he was readmitted, as it was found he had developed a glycosuria with acetone bodies present in small amount. His blood-sugar was 0·154 per cent. His diet was adjusted and he went out sugar free on carbohydrates 60 g., protein 60 g., and fats 148 g.

Ten months later he was readmitted for abdominal pain about half an hour after food, beginning as an ache in the region between the gall-bladder and the umbilicus, culminating in paroxysms of severe pain, doubling him up and radiating to the left. The paroxysms were accompanied by nausea, but no vomiting had ever occurred. Wasting, weakness, and polyuria developed, and no real progress was made on insulin and diet.

The history of previous pancreatic trouble, the character of the pain, especially its similarity in locality and radiation to that previously described, and the evidence of pancreatic disturbance, both in urine and stools, led Prof. Ellis and myself to discuss the diagnosis of pancreatic calculi, to be confirmed by the admirable X ray photograph (see figure) taken by Dr. M. H. Jupe. In view of the evidence of continued and progressive destruction of the pancreas (the inevitable sequel to calculous obstruction as shown in the cases recorded by Atkinson and Hirsch [2]), operation was decided upon, although not without some misgivings, as the blood-sugar persisted at 0·2 per cent. Lazarus [3] records 36 cases of glycosuria in his series of 80; Lancereaux [4] 12 in his series of 40.

Skiagram showing pancreatic calculi.

Operation.

General anæsthesia was employed, and the abdomen opened by a paramedian incision. Many adhesions were encountered, and the lesser sac was found to be obliterated by the previous effusion and drainage. The whole pancreas was enlarged, and on palpating the head the same peculiar crunching sensation described with the previous case was felt. It can best be likened to grasping a bag of marbles. Link described it in his case as "feeling like a bag of sand." The head of the pancreas was enlarged and extended below the duodenum. It was not the usual pale pink colour, but yellowish, and of a tough fibrous consistency. The duodenum was gently cleared upwards, and an incision made into the lower part of the head running up towards the neck. Small particles of grit were encountered in the substance of the head (shown in the X rays), but the duct was not discovered till the incision was deepened and carried upwards, when a large stone was dislodged, followed by a copious flow of dark-coloured glairy fluid with sandy particles in it. A Desjardin's forceps was passed into the dilated duct, and after several stones had been withdrawn passed with ease along the entire duct and could be felt in the tail of the gland. No entry into the duodenum could be made after all the stones had been cleared from the duct.

Some little hæmorrhage resulted from these manœuvres, and, recalling the toleration of actual drainage which the previous case had demonstrated, I passed a small tube 5 in. into the duct, and secured it by a plain catgut suture. The opening in the head of the pancreas was sutured round it in layers with chromic gut, and the tube, with a sheath of omentum sewn round it, was carried out of the abdomen by a stab incision in the right side opposite the pancreatic opening. The gall-bladder was rapidly drained.

Progress.

The patient stood the operation well; the pulse-rate never rose above 88, and the highest temperature reached was 99·2° F. on the second day. The pancreatic tube drained 3 oz. in the first 24 hours, 10 oz. in the next 24 hours, 8 oz. in the next two days, the tube being removed on the fifth day. Pancreatic secretion, which had no effect on the skin, continued for three days. The gall-bladder tube was removed on the ninth day, and the patient got up on the fourteenth day.

The blood-sugar improved and ten days later was found to be 0·143 per cent. Pain disappeared, appetite improved, and the patient gradually put on weight, his blood-sugar being controlled by insulin. His stools, large and of a peculiar dull silvery colour, indicated the persistent deficiency of steapsin in his pancreatic juices. Lazarus [3] found steatorrhœa present in 10 of the 80 cases in his series. The patient has returned to his work, and although on an adjusted diet and insulin, remains free from pain and in very fair health.

Examination of the fluid which drained away showed that the destruction of the pancreas was advanced. In the previous case recorded, the pancreatic fluid showed rapid starch, and slow protein and fat digestion. In this case protein and fat were not digested at all, and starch only slowly. The stones were found to be mainly calcium carbonate, with a very small admixture of phosphate. They were of the same type as previously noted, pale yellow in colour, studded like coral, friable, and the central ones roughly faceted at each end. No bacteria were discovered in them.

Comment.

Certain points of interest emerge from a consideration of this case.

1. The symptomatology repeats that of the previous case recorded, in that the pain began mildly as an ache half an hour to an hour after food and culminated in severe colic with sweating but no vomiting, a point of interest in comparison with gall-stone colic. The pain began in the epigastrium and radiated later to the left side of the abdomen. This left-sided radiation has been noted in other pancreatic disturbances, such as the subacute forms of pancreatitis and penetrating gastric ulcers involving the pancreas.

2. The operative findings, the string of soft stones in the main duct, the small particles of grit surrounding it in the lesser ducts, well shown in the X rays, and, beyond, the fibrotic back-pressure pancreas suggest an origin of these calculi other than recurrent attacks of subacute pancreatitis. More probably they are catarrhal in origin, from an ascending infection from the duodenum, and closely allied to those seen in the submaxillary gland and duct. Mayo Robson [6] originally gave the name "pancreolithic catarrh" to this condition. I operated on a case last year, in which that part of the head of the pancreas surrounding the duct of Santorini showed extensive calcification all over its surface. This area of the gland was

contracted below the level of the rest of the pancreas. It was causing recurrent attacks of pain, with slight jaundice from pressure on the common duct. The gall-bladder was healthy, a dilated common duct was explored, it contained no stones, but was stenosed opposite the calcified area. As the stools had shown no signs of pancreatic deficiency and the rest of the pancreas appeared healthy to the naked eye and exploring hand, a cholecystogastrostomy was performed. The patient has remained perfectly well since and has put on weight. This case appears to be one of pancreolithic catarrh limited to the area drained by the duct of Santorini, which does not anastomose with the duct of Wirsung in 10 per cent. of cases, as shown by Opie,[7] who quoted a case of acute pancreatitis limited to the area of the duct of Santorini.

3. The tolerance of the pancreatic duct to the presence, for five days, of a rubber tube which transmitted 21 oz. of juice in that time has, I think, a direct bearing on the theories and experiments of Kaufmann.[8] Not in any local infection, irritations, or foreign bodies are we to look for the source of that calamitous disease, acute pancreatitis, but rather a hæmatogenous origin, bacterial or possibly a perverted hormone stimulating and activating improperly the vital ferment, trypsinogen.

In conclusion, my thanks are due to Prof. Ellis. Dr. Jupe, and Dr. J. R. Marrack for their kind assistance in the investigation of this case.

Clinical and Laboratory Notes.

A CASE OF RHEUMATIC FEVER WITH MYELOCYTIC LEUCOCYTOSIS.

BY W. MACKAY, M.B., CH.B. GLASG.,
JUNIOR ASSISTANT TO THE MUIRHEAD PROFESSOR OF MEDICINE, GLASGOW UNIVERSITY; AND EXTRA PHYSICIAN TO OUT-PATIENT DEPARTMENT, GLASGOW ROYAL INFIRMARY.

THIS case is of interest on account of the unusual character of the leucocytosis which occurred in the course of the illness, the prevailing white cell being the myelocyte rather than the more mature polymorphonuclear leucocyte which is usually found in such cases.

A male patient, aged 37, was admitted to hospital on Nov. 27th, 1927. He was a hawker by occupation, living in a caravan and much exposed to the weather. He was a strong robust man and had enjoyed good health until six weeks previously when he developed an attack of rheumatic fever following a thorough soaking. At this time his left ankle- and knee-joints were swollen and painful, and after a day or two in bed he resumed his usual work before the pain had completely subsided. The pain in these joints continued with occasional exacerbations until ten days before admission, when severe precordial pain developed and he was forced to go to bed and remain there. While the precordial pain lasted respirations were embarrassed even at rest. After six days in bed this pain disappeared and he was conveyed to Glasgow by caravan from the North of England, a distance of 140 miles.

On admission he was very ill, he perspired freely, and suffered from great general weakness and loss of appetite. The right thigh, knee, ankle, arm, and left mandibular joints were very tender. He had a cough with copious mucoid spit, and in the left lung numerous coarse, moist râles, indicative of bronchitis, were heard. Albumin was present in the urine. The cardiac area was well within normal limits, the sounds were forcible and of good tone, and there was no evidence of endocarditis or pericarditis. Nine years earlier patient had had pneumonia but there was no history of previous attacks of rheumatism.

After the first few days in hospital the joint pains subsided to a great extent in response to treatment with sodium salicylate and the patient, although still very ill, seemed to be improving. However, on Dec. 1st pericardial friction was noted and the bronchitis assumed the character of a capillary bronchitis. The pericardial friction disappeared after two days and there was never any evidence of pericardial effusion or of cardiac dilatation. On the 5th there were signs of pneumonic consolidation at the base of the left lung and it was noted that there was now a leucocytosis of 53,000 white cells, although on the 3rd examination of a blood film gave evidence of an apparent increase in the number of white cells. On the 3rd, also, a tender swelling appeared over the right costal margin in the nipple line and it was this which suggested a differential count of the white blood corpuscles. By the 7th the consolidation of the lower lobe of the left lung reached as high as the interscapular region and there was gaseous distension of the abdomen. The swelling on the costal margin was now not so tender and it had rather lessened than increased in size. Its nature still remained unknown. From Dec. 1st the patient was obviously critically ill. He was sleepless, restless, and latterly delirious. The temperature varied from day to day and ranged from 100° to 104° F. The pulse-rate varied from 100 to 148, and the respirations from 28 to 52. The patient died on Dec. 8th.

The spleen and superficial lymph glands were never palpable and there were no hæmorrhages from mucous surfaces and no purpuric spots. The Wassermann reaction was negative and there was no growth on blood culture after seven days' incubation. On Nov. 28th and 29th the leucocyte count was within normal limits, but by Dec. 3rd a leucocytosis of approximately 35,000 white cells was noted on examination of a blood film and on that date also the myelocytic nature of the leucocytes was discovered for the first time. The patient also had a fairly profound anæmia and the colour-index equalled unity.

Table of Blood Counts.

Date.	Red cells.	White cells.	Hæmoglobin.	Colour-index.
1927.				
Nov. 28th	—	6,200	—	—
„ 29th	2,200,000	5,000	47%	1
Dec. 5th	2,260,000	53,200	44%	1
„ 6th	—	27,800	—	—
„ 7th	—	34,200	—	—
„ 8th	—	27,000	—	—

Examination of blood films taken on Dec. 3rd, 6th, and 8th revealed the red cells to average 9·2 microns in size. They all stained well, although some polychromasia was noted in a number of forms. Seven megaloblasts and six normoblasts were present in counting 3000 white cells. Differential counts, each on 1000 white cells, were carried out on the above dates and the various forms of white cell were found to be present in the following proportions.

Table of Differential Counts.

Type of cell.	Dec. 3rd.	Dec. 6th.	Dec. 8th.
	Per cent.		
Neutrophile—			
Polymorphs	3·2	3·1	3·2
Metamyelocytes	3·9	4·3	3·6
Myelocytes and premyelocytes	78·7	87·5	89·4
Eosinophil myelocytes ..	0·1	—	—
Basophile myelocytes ..	0·2	—	—
Myeloblasts	1·9	0·1	—
Monocytes (large hyaline cells)	0·9	0·8	—
Lymphocytes	11·1	4·2	3·8

Permission for post-mortem examination was refused.

Discussion.

The case was regarded as one of rheumatic fever with pericarditis and pneumonia, but the former complication seemed to subside satisfactorily. It is not obvious why the patient did not recover as the complication of pneumonia is rarely a cause of death in rheumatic fever. Blood films were not examined until Dec. 3rd, when the swelling appeared at the costal margin so that it is not known at what date the myelocytes appeared first in the circulating blood, but it was thought that the leucocytosis was determined by the advent of the pneumonia.

It is well known that immature leucocytes can appear in the circulation in the general leucocytosis of acute infections—e.g., pneumonia and acute rheumatism—but as a rule in these diseases the myelocytes are relatively few, the predominating cell being the neutrophile polymorph. Naegeli [1] quotes a case of croupous pneumonia published by Türk in which the number of myelocytes reached 11·9 per cent. of the total white cells, and another case, one of necrotic tonsillitis complicated by severe anæmia, observed by Morawitz, in which the neutrophile myelocytes numbered 20 per cent. of 22,100 leucocytes per c.cm. In both of these cases the number of myelocytes present in the blood was regarded as being extremely high. Neutrophile myelocytes also occur in varying proportions in severe forms of anæmia and in invasion of the bone-marrow by tumour metastases, but it is unusual to get such a high percentage as in the case now put on record.

In other rather different conditions high neutrophile myelocyte counts have also been recorded. Prof. W. K. Hunter [2] quotes a case of fracture of the leg observed by Simon in which the myelocytes present in the blood numbered 15·2 per cent. of 50,000 white cells. In this case the blood returned to normal on recovery. He also records the case of a girl, aged 5, with an enlarged spleen in whose blood 24 per cent. of the white cells were neutrophile marrow cells. To begin with, she was thought to suffer from leukæmia, but she made a good recovery, and ten years later was in robust health.

It is in leukæmia, however, that the neutrophile myelocyte is present in the blood in greatest numbers, and rare cases have been noted in which this cell is the prevailing cell (Alder, quoted by Piney).[3] A leukæmic condition of the blood is found in myeloid chloroma and myeloid myeloma, and in this connexion the possibility of the tender swelling over the costal margin being a chloroma or myeloma was considered, but the character of the blood picture and the fact that the swelling seemed to be situated over the cartilaginous part of the costal margin did not appear to indicate any association between it and the myelocytosis. In the absence of histological examination of the bone-marrow no definite conclusions can be arrived at from the data afforded by this case as to the cause and significance of the blood picture, but it is thought that it may be due to a toxic or chemiotactic influence on the bone-marrow, affecting particularly the neutrophile hæmopoietic tissue. However, the fact that a neutrophile myelocytic leucocytosis may occur in the course of rheumatic fever complicated by pericarditis and pneumonia is of interest and worthy of note.

I gratefully acknowledge my indebtedness to Prof. Hunter for permission to publish this case.

A NOTE ON ULTRA-VIOLET RADIATION IN THE TREATMENT OF PEMPHIGUS NEONATORUM.

By A. W. Gregorson, M.D., F.R.F.P.S. Glasg.,
DEPUTY SUPERINTENDENT, NORTH MIDDLESEX HOSPITAL, EDMONTON.

Pemphigus neonatorum may be simple or may be serious, and is one of the conditions which have a tendency to linger a long time, may be for years, in connexion with a maternity department. There may be a period of apparent immunity extending over months and no case occur; then, without any obvious cause, a new outbreak takes place.

The degree of severity varies considerably; in some cases one single bleb, in other cases hand and foot are invaded. It is rare that one finds the disease to end fatally. Recovery is the rule, even in patients showing extensive areas of infection. Sometimes one has observed the initial blister to occur in the region of a nerve, particularly on the upper arm, on the hand and foot. Consequently, one is prompted to ask if the condition is in the nature of a toxic neuritis, resembling herpes zoster; or is it an infection during labour; or is it brought to the bedside by the nurse, midwife, or is it air-borne?

From personal observations I have formed the opinion that pemphigus neonatorum is a toxic neuritis and constitutional in origin. The disease is found most commonly in the infants of women who are in a low state of health at the time of confinement. The blebs first make their appearance in the region of the musculo-spiral and posterial tibial nerves, sometimes after the infant's first bath. In all cases observed the umbilical cord has been beyond suspicion. Considerable investigations have been made at this hospital to determine whether the nurse-midwife has been the medium of infection, and no evidence has been found that she is.

As regards treatment, it has been found that the most successful procedure is to keep the infant dry and to avoid bathing of any form. The necessary toilet is carried out with oil, and dryness maintained over the whole body. Bathing spreads the disease. Ointments, lotions, powders in various combinations have been tried successively without any very encouraging results. A series of cases have been treated by ultra-violet radiation with great success. The blebs soon dry and disappear, and the infant improves in general condition. The mercury-vapour lamp was used twice weekly, at a distance of 2 feet for 3 minutes, increasing by 1 minute to 6 minutes.

The main purpose of this short note is to recommend this form of treatment as being efficient, easy of application, cutting short the disease, and invaluable in removing a source of anxiety to the mother.

A CASE OF PARTIAL GASTRECTOMY FOR PYLORIC ULCER,

FOLLOWED BY TWO JEJUNAL ULCERS PERFORATING AT INTERVALS OF SIX MONTHS; RECOVERY.

By Victor Penrose Robinson, B.M., B.Ch. Oxf.,
SENIOR HOUSE SURGEON, ROYAL INFIRMARY, SUNDERLAND.

The case recorded below appears to be of sufficient interest to warrant publication.

First Operation.—In January, 1927, a man, 25 years of age, was operated upon by Mr. S. Ritson in Sherburn Hospital for an ulcer on the duodenal side of the pylorus. The operation performed was Bilroth II.—a pylorectomy with closure of the ends and a posterior gastro-jejunostomy. He recovered.

Second Operation.—He had no further symptoms until he was seized with severe abdominal pain at 11 A.M. on August 4th, 1927, on which date at 8 P.M. he was admitted into the Sunderland Royal Infirmary with a perforated jejunal ulcer under the care of Dr. Ayre Smith, senior surgeon. His bowels had acted on that day and he had vomited several times. There was marked shock, with cold clammy sweat; thoracic respirations; and the abdomen was rigid but resonant. Temp. 98·8° F., pulse 96, resp. 28. A rectal examination revealed nothing abnormal. An immediate operation was performed. On opening the abdomen in the midline, gas and fluid escaped. A perforated ulcer, ¼ inch in diameter, was found in the jejunum close to the anastomosis. It was sutured and covered with omentum, and the abdomen closed in two layers without drainage. He recovered and was discharged on August 27th. His bowels were kept acting with liquid paraffin and he remained well for five months.

Third Operation.—On Jan. 25th, 1928, he began to have abdominal discomfort and on the 28th he was readmitted into the infirmary with severe epigastric pain, which had come on at 3 P.M. the same day. He had vomited and the pain was exactly like that which he had experienced on August 4th last. At 11.30 P.M. he was found to be suffering from severe shock with a cold sweat. Temp. 97·6° F., pulse 86, resp. 24. The tongue was moist but furred; and the abdomen was rigid especially in the upper half, which was tender, particularly to the left of the midline.

No free fluid was made out. A second perforation was diagnosed. At midnight I opened the abdomen through the old scar; gas and fluid escaped. A second perforation was readily found on the anterior surface of the jejunum distal to the anastomosis. This was sutured with catgut and covered with omentum. The fluid was mopped out and a rubber drain was inserted into the lower end of the wound and was left in for 24 hours. He made a good recovery and on Feb. 10th, while on light diet, a test-meal revealed the following:—

	Before test-meal.	After test-meal.
Free acid	24	55
Combined acid	16	24
Total acidity	40	79

As the acidity in an average normal person is given as free HCl 20–40, combined acid 25, and total acidity 40–50,[1] this test showed that there was still hyperacidity of the gastric juice, which the gastro-jejunostomy had failed to cure. A gastro-enterostomy usually reduces the hyperacidity by permitting a quicker emptying of the stomach contents and by allowing a reflux of the alkaline bile and pancreatic juice into the stomach. A pylorectomy cannot be expected to reduce the acidity of the gastric juice, seeing that the HCl is secreted by the oxyntic (acid-producing) cells, which exist chiefly in the middle half of the stomach. Apart from the continued hyperacidity there was no other cause found for the recurrence of the ulcers. He was therefore advised as to his diet and it was suggested to his medical attendant that he should have alkaline treatment continuously to reduce the persistenthy peracidity.[2] He was discharged on Feb. 13th.

This note appears by courtesy of Dr. Ayre Smith.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY.

MEMBERS of the British Psychological Association were invited to attend the meeting of this Section on March 29th, when Dr. R. LANGDON-DOWN, the President, took the chair, and a discussion on the

ÆTIOLOGY OF ALCOHOLISM

was opened by Dr. BERNARD HART, who defined alcoholism simply as the continued and excessive ingestion of alcohol, and reviewed the answers that had been offered to the question: Why do people take alcohol to excess, or, indeed, at all? Some answers had emphasised heredity, others habit and the vicious circle, and others again psychological conceptions. It seemed that the last were tending to exclude the others unduly. The modern psychologist held that the forces which drove men to take excessive alcohol were, in some measure at least, identical with those which drove them to take it at all. Therefore the cause of alcoholism must be sought by inquiring into its effects. F. G. Stockert had divided these into two groups: (1) psychomotor stimulation coupled with an expansive and euphoric affective tone; and (2) a dissociative, dulling process extending to paralysis. How far the psychomotor stimulation was real was disputed, but ergographic experiments had shown that small doses produced an actual increase in the output of work for a short time. The subjective increase was, however, much greater and more important. The astonishing efficiency of alcohol as a refuge was apparent not merely in the way it met an immediate need, but in the continued service it afforded so that many of the symptoms of chronic alcoholism and of the alcoholic psychoses themselves gave further aid in the escape from reality. Possibly the euphoria was only to be explained in chemical terms, and possibly it was in part a secondary result of the removal of inhibitions which underlay many of the phenomena of alcoholism; there was relief from such morbid inhibitions as shyness, and a failure of those inhibitions which control immediate urges in the interest of remote ends and hence exhibition of conduct at the mercy of every passing desire. The sociability produced was one of the principal aims of taking alcohol. Psycho-analysts held that alcohol tended to destroy sublimations and aid mental regression, that homosexual factors played a prominent part, and that regression might proceed to various depths. It was debatable how far any particular effect of alcohol was to be regarded as an aim and how far it was a price paid in the achievement of some other end. The psychological aims did not exhaust the whole problem and other factors required careful consideration. The first of these was the essential craving, which did not arise prior to experience of alcohol and disappeared after prolonged abstinence. It did not seem susceptible of any satisfactory psychological explanation. The closely similar phenomenon of morphinism was certainly attributable to the formation of chemical products which required further doses to counteract their effects. Most investigators were agreed that in certain types, such as manual workers, the craving might be sufficient to induce alcoholism in the absence of any "refuge" urges. The psychological aims, craving, and habit constituted the "exciting causes." It would seem easiest to explain the "predisposing causes" on the assumption that alcoholism, neuroses, and psychoses were alternating methods of achieving an escape from a reality to which adaptation had been found impossible. Since all of them occurred more often in some stocks than others, a constitutional factor must be admitted. Kretschmer had divided chronic alcoholic into a pyknic, cyclothymic "sociable" type and a schizoid, difficult and nervous type. Many authors considered this classification to be of paramount importance, and distinguished sharply between the taking of alcohol as a beverage and as a drug, between the man who drinks as a custom and the man who cannot stop. In practice, however, the factors were inextricably mingled. Dipsomania had been held to be a manifestation of epilepsy, of psychasthenia, and of manic depressive insanity, while others regarded it as a symptom-complex and not a disease sui generis. There was therefore a wide range of opinion as to the relative importance to be assigned to the various factors, ranging from MacCurdy's dictum, "The alcoholic is, before he even touches a drop, an abnormal person," to those who maintained that alcoholism might arise quite fortuitously in a normal man. The solution was not to be found in any single or specific mechanism, but alcohol might serve several ends, and various types of individual, on account of their hereditary constitution or prior history, might be more or less likely to avail themselves of alcohol as a means of securing those ends and hence to engender processes to which habit would ultimately contribute its part.

The Psycho-analysis of the Alcoholic.

Dr. E. GLOVER, dealing with the problem from the psycho-analyst's point of view as a maladaptation rather than a disease, said that all the primary features of alcoholism represented fundamentally an attempt on the part of the individual to extricate himself from an impasse. From the environmental side it was a flight from reality, which coincided on the instinctual side with an increase in phantasy formation. Clinical differences could be related to the completeness or periodicity of this withdrawal from reality. The investigator was too apt to dismiss the drunkard's phantasy life by calling him "an inveterate liar," and to obscure its significance by the word "confabulation." Hallucinations and delusions indicated an attempt to substitute a new reality for the old, or to project into reality the mo

ainful elements of phantasy life. The so-called eakness of will, lack of decency, and moral deteriora-on were the gratification of previously inhibited apulse. Withdrawal from reality activated phan-sy corresponding to definite layers of psychic velopment, so that an element of regression was ways present, heading towards some infantile end. ggressive and sexual instincts were manifestly atified in drunkenness. Projection was a character-ic feature of all alcoholic states. The chronic inker shelved responsibility and attributed his bits to his social or marital difficulties. The eudian school, while admitting the social, habitual, d economic factors in alcoholic ætiology, held at these were "exciting" causes, with internal, stinctual frustrations as the real underlying cause. ycho-analytic investigation of the alcoholic always owed a modification of instinct in the form of tense preoccupation with oral images and phantasies. ie alcoholic had made a bad start and was always mpered by a tendency to regression, giving rise to ertia in development. Thus the next stage found m already handicapped, and in this stage anal otism and anal sadism were heightened. He then me to the third or infantile genital stage with the uble difficulty that his impulses were archaic and s reaction to disappointment excessively severe. hen the incestuous climax to infantile sexuality as shipwrecked on castration anxiety, the tendency regression was fully established, and the ground epared for future miscarriages of sexual instinct in ult life. One of the dire necessities that drove man to alcohol was the need to overcome excessive arges of castration anxiety. The drunkard's loud astfulness afforded compensation for inner insuffi-ency or impotence (symbolic castration). When the o was damaged the anxiety broke through in assive charges. The ego of the alcoholic was over-arged with narcissistic libido, and he hardly dared ve anyone who could not be identified with the self. ie stage at which the ego began to lag in develop-ent was a second factor in the variety of alcoholic anifestations. Many of the guilts and anxieties of coholics indicated some interference with the nction of conscience; the constant use of pro-tion made their consciences seem turned inside t. The alcoholic either had a more severe primitive nscience than normal, or else was unable to cope th the drive of primitive impulse and landed nself in situations of self-punishment. The former ficulty was seen in the depressed type of secret nker and the latter in chronic alcoholics. The use of alcohol invariably led to self-punishment, ch as organic illness or economic failure. Alcohol s chosen as a surrogate of sexuality or a method of ort-circuiting it, while releasing the pressure of pression and reversing processes of sublimation. cohol owed most of its attraction to the fact that was primarily well-adapted to overcome castration xiety, although in the long run it defeated its own l by bringing about impotence and death (symbolic stration).

The Recent Decrease in Alcoholism.

Dr. E. MAPOTHER doubted whether from the stand-int of psychology any advance had been made for ousands of years in the understanding of the oblem of why men take alcohol. He quoted ripides to show that euphoria and the effect of ohol in submerging conflict and cloaking reality d been well known to the Greeks. Much of the eged advance had been no more than the turning poetry into prose and platitude into jargon, the fusion of tabloid thought among meagre minds. e dangerous drinkers were those who looked for se and sought peace and ensued it, and also those o took alcohol "on doctor's orders." Normal nkers took alcohol because, although they knew it be bad, it made them feel good. Furtive alco-lism was only found in those who were already normal. Alcohol had been called the anæsthetic the poor, but was quite as popular among the well-do and was not regarded in such a negative light by the poor; they drank to regain their illusions. Most alcoholism that sought negative effects was morbid, but much of it was at first positive and later became increased by habit. Important questions were: Why did alcohol induce euphoria; what influences encouraged and discouraged the use of alcohol by those in quest of euphoria; why did alcohol act as a narcotic; how often was drunkenness designed to dull grief, remorse, or fear, or how often was it the accompaniment of a particularly painful memory or some current conflict? The first question was only to be tackled by the neurologist and the biochemist: another phase of the search for happiness in a bottle! The modern scientific view was that the effect of alcohol in all stages and on all parts of the nervous system was depressant; that it was a narcotic drug. The view of Dr. Stockert was more cheerful and seemed to Dr. Mapother sound. Euphoria did not occur in the early stages of other gradual reductive conditions like fatigue or neurasthenia. Beyond doubt, social influences were the most important in promoting festive alcoholism. He quoted figures to show the striking decrease in the consumption of alcohol between 1914 and 1923. If all the drunkards in the country had gone dry it could not account for the amount. Alcoholism was conditioned by social tradition on the one hand and the cost of getting drunk on the other. A reduction of alcoholic morbidity to about one-third of its pre-war incidence had occurred. Temperance and intemperance were national characteristics and not innate, as was shown by the fact that 13 per cent. of all psychoses among Gentiles were alcoholic, and among Jews only 2·3 per cent. The psychoses of the solitary drinker were less rare, relatively, among Jews; it was the acute mental disorder due to heavy social drinking that was rare among them. Dr. Mapother had not been impressed by the existence of any specific craving independent of an association of ideas, nor had he seen benefit from the giving of alcohol in early delirium tremens. It was possible that alcoholic tolerance depended on the presence of some protecting lipoids circulating in the blood. If so, they were obviously more likely to be preventing the entry of alcohol into the cell than producing reverse effects. They were no more likely to produce a craving for alcohol than would a mackintosh for rain. He had not found a history of overt homosexuality in alcoholics, nor that this formed a feature of their delusions and hallucinations.

Types of Drinkers.

Dr. H. CRICHTON MILLER said that in the broadest sense it might be held that alcohol was taken to modify the feeling tone, in the realm either of somatic or of emotional experience. The resulting modifications might be referred to two chief mechanisms: (1) interruption in continuity of functioning of the nervous system, ranging from incoördination to dual personality; (2) a repressive change whereby the activity of cortical centres was subordinated to thalamic control, acquired inhibition succumbing to instinctive pressure and conceptual thinking being submerged by perceptual activity. It might be supposed that these changes depended on two mechanisms; the change in intracranial pressure and the hypothetical alteration in synaptic functioning due to altered chemical constitution of the cerebro-spinal fluid. The latter would explain the dissociative phenomena. There was no experimental knowledge of the specific effect of alcohol on the relative tension in intracranial and visceral systems. It might be supposed that the vascular tension was differently affected in cortex and midbrain. Any effortless oblivion was an alluring retreat from most forms of conflict. A retreat from conceptual to perceptual ideation was often pleasant, if not desirable. The introvert found in alcohol a chemical solvent of the inhibitions that dammed up his self-expression; the man with an inferiority sense felt himself 100 per cent., and the psychasthenic derived from alcohol a temporary rise in the threshold of consciousness. The demand of two groups for alcoholic euphoria

was based on physical states—viz., the hypopietic and the subthyroidic. Probably low blood pressure entered into a large proportion of all cases of alcoholism, especially amongst women. Presumably the mechanism of satisfaction in subthyroidics was a general vasomotor stimulation. Hyperthyroidics did not tend to be steady drinkers. In the sensorial type, who sought modifications of sensory experience, came those who alternated alcoholism with auto-erotism. The rebel drank because his father had been a temperance reformer, and for him gold cures and injections of alkaloids were the height of absurdity. There were three chief groups of intermittent drinkers: the epileptic, the dual personality, and the manic-depressive. The last were resistant to all treatments. Drinking might be a feature of either phase, but never of both. No simple formula and no single ætiology would cover the pathogenesis of alcoholism.

Discussion.

Prof. G. M. ROBERTSON agreed that there was no single formula, pathology, or therapeusis for alcoholism. He thought that there was an hereditary lowering of mental function, so that the individual lost the capacity of dealing with his difficulties and so gave way. He doubted whether the craving for alcohol were to be compared with the chemical change in the blood which produced the morphia craving.

Dr. W. H. STODDART defined alcoholism as a state in which a person feels the need of alcohol, and quoted cases to show that this need might be felt imperatively before alcohol had been taken. To cut off alcohol too severely in cases of delirium tremens might be a serious thing.

Dr. A. E. CARVER said that patients who had alcohol without knowing they were having it became euphoric. He believed that the craving was felt before inbibition; it was natural for a man to crave for something to relieve him when he felt things were "getting on top of him."

Dr. T. A. ROSS said that the alcoholic was not uncomfortable when his alcohol was cut off, provided he were being looked after and had confidence in his doctor; only if he were overcome by some overwhelming emotion he would have the craving, which was wholly psychological.

Dr. J. A. HADFIELD said that alcoholism appeared in individuals who found the responsibilities of life too heavy. This formula linked up with many of the other ætiological factors: the temperamental, the hereditary, the physical, and the psychological. The individual who never really grew up, never got confidence, or that sense of security and protection that every child ought to have, naturally developed a fear of life in general and tended to become fixated, seeking for security and escape from life. He did not get love for others in his childhood; he loved himself or persons of his own sex (which was self-love once removed), and therefore he could not face the difficulties of life. He took to alcohol because it produced euphoria, the forgetting of difficulties and the liberation of those thalamic factors which made life so jovial.

Dr. M. LEAHY described success with suggestion treatment, replacing the idea, "I need drink, I must have drink," with the idea, "I do not want to drink." This would not cure every case, but if the patient were sufficiently receptive it would prevent him from drinking.

Dr. J. D. ROLLESTON referred to the historical aspects of alcoholism, which in antiquity had been almost entirely convivial and to some extent religious, except where associated with prostitution. He mentioned also the importance of alcoholism of therapeutic origin.

Dr. W. BRANDER suggested that euphoria might be due to alterations in the intracranial blood pressure or to the presence of alcohol in the cerebro-spinal fluid, comparing it with the euphoria of general paralysis and disseminated sclerosis. The body adapted itself to alcohol in many ways other than mental—e.g., the digestive secretions and the pH became altered, and being thus adapted it was uncomfortable in the absence of its habitual stimulus.

MANCHESTER MEDICAL SOCIETY AND LIVERPOOL MEDICAL INSTITUTION.

AT a joint meeting of these Societies, held at Manchester on March 8th, a paper on

Colloidal Lead

was read by Prof. W. J. DILLING (Liverpool). He said that the following standards had been approved in judging the suitability of colloidal lead preparations for the treatment of cancer: (1) that intravenous injections representing 0·025 to 0·05 g. of lead per kg. of body-weight should be tolerated by rabbits without local irritation or immediate or late symptoms; and (2) that similar injections in cats should cause neither respiratory nor circulatory disturbance. The latter, he said, was the greater safeguard since a decided, although brief, fall in blood pressure, synchronous with and due to impairment of the contractility of the auricular muscle, resulted from injections of ionised lead solutions and many colloidal lead preparations. Tracings from cats showed this effect on the auricle and the consequent diminution of the pulse-wave and of blood pressure; frequently repeated large doses of "approved" lead colloids could produce similar effects. Microscopical examination of the tissues of mammals injected with lead colloids revealed fine granules, and microchemical tests indicated that these were colloidal lead. A series of microphotographs showed them free in the blood-vessels and inside leucocytes. The spleen contained large numbers in the splenic pulp, free in the blood sinuses, forming extranuclear rings in the splenic cells and concentrated in the phagocytic splenocytes; the malpighian corpuscles contained relatively few—and more minute—particles, or sometimes none. The liver contained particles but their distribution varied; they occurred in the blood sinuses, in the hepatic cells, and in the endothelial cells of Kupffer. In the kidney, particles had been found within the glomeruli and punctuating the outlines of the convoluted tubules. This organ almost invariably showed evidence of degeneration of the secreting cells of the cortical tubules, loss of nuclear staining and occasionally necrosis; glomerular congestion and hæmorrhage had also been observed. Particles also occurred in the lung, but owing to the presence of carbon granules their exact distribution was uncertain. In no other tissue had granules been found with certainty. Microphotographs of the spleen and the liver of a man who had lead acetate poisoning had also exhibited granules in comparable positions. Chemical analysis of mammalian tissues from these experiments with the chromate method confirmed the belief that the lead was in highest concentration in the spleen, liver, lung, and kidney and in the blood. The percentage in other tissues examined, including bone, was relatively low, but indicated the commencement of excretion by the bile and urine. The lead granules were apparently concentrated chiefly in the reticulo-endothelial system but it had not yet been possible to trace them to the endothelial cells of the lymph glands, of bone-marrow or of connective tissue. The only organ in which histological damage was apparent after large colloidal lead injections in animals was the kidney, a fact of considerable clinical importance.

Mr. F. J. S. HEANEY (Liverpool), in a paper on

Gastric and Duodenal Cases,

described a series of 183 consecutive cases of gastric and duodenal ulcers operated on by him during the past four years. With the assistance of Dr. R. Aidin he had followed them up and had ascertained the

esults after a year in about 90 per cent. of them. The cases comprised 33 perforations, 65 chronic uodenal ulcers, and 85 gastric ulcers. Among the 3 perforations the early mortality was 8·7 per cent., nd the follow-up showed good end-results in 0 per cent. of the remainder. In 31 of the 33 cases, n addition to repair and pelvic drainage, gastro-nterostomy was performed. There were two nsatisfactory end-results: (1) a case in which gastro-nterostomy had not been performed, and (2) a case here the gastro-enterostomy opening contracted; oth of these required a further operation. For hronic duodenal ulcer the operation done consisted f a vertical gastro-enterostomy running into the owest point of the great curvature, in some cases ith infolding of the ulcer and in some with append-ctomy. The mortality in hospital was 3 per cent., lmost entirely from post-operative pulmonary omplications. The "follow-up" showed good end-esults in 90 per cent. of those leaving hospital alive. here were two gastro-jejunal ulcers (3·1 per cent.), ne arising four months and one four years after astro-enterostomy; both were cured by partial astrectomy. The other unsatisfactory end-results ere seen in patients who for one reason or another id not have appendectomy performed at the same me as gastro-enterostomy. Present symptoms in lmost all of them were suggestive of recurring ppendix trouble. This, however, might have been coincidence as no such results were seen in the cases f gastro-enterostomy for perforation, in none of which he appendix had been removed. Chronic gastric ulcers aried so much in clinical picture and operative ndings that for the purpose of useful comparison they ere subdivided into complicated and uncomplicated. he uncomplicated were small or moderate-sized lcers situated at the pylorus or near the lower part f the lesser curvature, without serious adhesions. he complicated were the larger ulcers of the posterior all, those with perforation of neighbouring structures, ose situated high in the stomach, those accompanied y cholecystitis, ptosis, or hour-glass contraction. f the 55 uncomplicated cases, gastro-enterostomy as performed in 54, with 2 deaths, both from ulmonary complications. In the remainder the d-results were uniformly satisfactory. Mr. Heaney iefly referred to present views on ætiology of ulcers, d the relation of chronic gastric ulcer to gastric ncer. In his series of cases there was no instance of ncer being found after simple gastro-enterostomy r gastric ulcer, nor was there any instance of ncer arising after excision or gastrectomy where the ecimen removed at operation was reported histolo-cally non-malignant.

Dr. N. B. CAPON (Liverpool) described a case of ontiasis ossea (diffuse osteitis type) in a boy of 3 years.

MANCHESTER PATHOLOGICAL SOCIETY.

AT a meeting of this Society held on March 14th, r. F. H. WESTMACOTT, the President, in the chair, address on

Normal and Abnormal States of the Connective Tissues in the Breast

as given by Sir GEORGE LENTHAL CHEATLE.

Dealing first with the general supporting tissue of e breast, he said that, like fibrous tissue elsewhere, was liable to develop sarcoma and fibroma, but ese were not true breast changes. A sarcoma could ly be diagnosed from a fibro-adenoma by a whole tion of the breast. It was impossible to separate perplasias of the true breast connective tissues om the accompanying epithelial hyperplasias. The thological importance of the combination was seen the papillomata. Physiological influences had a at bearing on the generalised (and as a corollary the localised) hyperplasias. In the section shown the breast of a woman aged 42, which most ople would say was in a state of chronic mastitis, o points were striking; first, the presence of fibro-adenomata, formed and forming; and, secondly, the hyperplasia of the pericanalicular and peri-acinous connective tissue. A consideration of the normal breast at puberty and at birth would show physiological relationships between the formation of fibro-adenomata at puberty on the one hand and the so-called chronic mastitis on the other. Both of these conditions were manifest in the specimen described. In the normal breast at puberty there was an enormous increase of acini and a hyperplasia of the peri-canalicular and periacinous tissue, amongst which lymphocytes were common. The fibro-adenomata which were so common at puberty consisted of hyperplasia of the pericanalicular and periacinous tissues, and in some of them new acini developed so that in the pathological part of the breast there was occurring only an irregularity of the physiological activity progressing in the rest of the same breast. Lobulation of fibro-adenomata was not due to out-growths from the original tumour but to primary similar and later changes in the breast tissue adjacent to it. The presence of lymphocytes amongst the hyperplastic pericanalicular and periacinous tissues in the normal breast at puberty gave all the morpho-logical characteristics of so-called chronic mastitis, and was thus evidence that "chronic mastitis" was an incorrect term.

At birth it was impossible to distinguish a male from a female breast and in both a desquamative epithelial hyperplasia filling the ducts, together with a hyperplasia of the pericanalicular and peri-acinous connective tissue containing lymphocytes, gave an appearance which, in the adult, would certainly be diagnosed as chronic mastitis. This condition in the adult was not an inflammation but a physiological change, become pathological by reason of its irregularity and its excess of the normal. In passing, it was pointed out that most breasts of the age to which this condition belongs only appeared nodular on the surface owing to hypertrophy of the ligamenta suspensoria of Cooper, which isolated fat nodules. If the skin were undercut the nodularity disappeared. Such breasts were never adherent to the pectoral fascia, as might be the case in the rare nodular breasts which were the seat of carcinomata.

The elastica was next considered. Hyperplasia might be (1) general and associated with carcinoma or with dysgenetic epithelial hyperplasia, or (2) local, in conjunction with carcinoma, epithelial hyperplasia, Paget's disease of the nipple, or hyperplasia of the intra-elastica. It did not represent a local resistance to the malignant invasion. Finally, hyperplasia of the intra-elastica was described. In this state it often underwent early degeneration. Hyperplasia of this tissue did not affect the whole breast and it might not form a localised tumour. On the other hand, it might form one kind of intracanalicular fibro-adenoma (which the lecturer believed to be common), and also certain uncommon, unbranching papillomata.

SEAMEN'S HOSPITAL SOCIETY.—The Duke of York presided at the annual court of governors of this Society held at the Hotel Cecil on March 20th. The new Queen Alexandra Memorial Hospital (60 beds) for seamen at Marseilles, opened on Jan. 1st, with a British resident medical officer, secretary, matron, and nursing staff, was, said the Duke, the seventh establishment for which the Society was responsible. Science was making seafaring safer but there were still accidents and diseases, to relieve which the Society existed. In its hospitals it helped people of many nations, thus making friends for Britain all over the world. The Society had received some £4000 from the Hospital Savings Association, but it was, he said, the duty of everyone to help the seamen. Sir Arthur Clarke submitted a report showing that over 5000 in-patients and 23,000 out-patients had been treated during the year for an expenditure of £80,000, while £6000 remained to be carried forward. The French Ambassador, who proposed thanks to the Duke, congratulated the Society on its new hospital at Marseilles. Mr. Neville Chamberlain (Minister of Health) seconding, said the seaman had a hard life, with a mortality from disease 50 per cent. greater than that of landsmen, and fivefold theirs from accident.

Reviews and Notices of Books.

HEALTHY GROWTH.

By ALFRED MUMFORD, M.D., Medical Officer of Manchester Grammar School. London: Humphrey Milford, Oxford University Press. 1927. Pp. 348. 16s.

THE author explains the scope of his book by giving it the subtitle of a Study of the Relation between the Mental and Physical Development of Adolescent Boys in a Public Day School. The work is scholarly and original both in subject matter and method. Dr. Mumford has been at pains to acquaint himself with the work of previous anthropometric investigators, and the methods which he has employed are to a large extent based upon the experience of others; but the scope of his observations is wider than that of any of the earlier observers.

The purpose of the book can best be grasped from the author's own words: "From 1909, underlying the work at the Manchester Grammar School, there has been a desire to find standards by which to judge the capacity of the boys to withstand the pressure of modern school life, not only without injury, but with positive benefits. We have never abandoned the belief that mental, physical, and moral growth sprang from the same source, were mutually helpful, and were influenced widely by variation in the degree to which they were stimulated." The author has made use of a number of measurements and tests in his efforts to assess the physical resources of growing boys. Of these the more important are measurements of height, weight, chest girth, and vital capacity; to these are added measurements of the specific gravity of boys, made in a swimming bath, from which is calculated a "buoyancy index," measurements of the electrical conductivity, and moisture loss of the human skin, and the "persistence test" devised for the physical examination of air pilots. The author distinguishes three types of body shape in school-boys, which he calls the wineglass, test-tube, and barrel shape. These varieties seem to correspond closely with the athletic, asthenic, and pyknic types of Kretschmer. The types differ from each other in physical capacity and resource, in mental and also in moral qualities. Boys with the test-tube-shaped chest require more sleep than their fellows. "Moreover, since they often retain the uncontrolled and undirected emotional characteristics of childhood for a longer period than their better-balanced companions, whose total output of mental energy may be less, special consideration is demanded when they are in disgrace, and when the question of punishment arises."

The essence of Dr. Mumford's work, in which also resides the novelty of his outlook, consists in the correlation of observations upon the boys' physical, intellectual, and moral growth. This correlation demands a close coöperation between the medical officer, the masters and, in a day school, the parents, whose respective opinions and reports are collated in the author's conclusions. It will therefore be seen that the educative scope of Dr. Mumford's conceptions and methods is likely to prove widespread. Included in its orbit are not only the staff of the school and the boys that pass through it, but the boys' parents, who, in a town like Manchester, will constitute an ever-widening circle of influential people. These, in so far as they are asked to collaborate in the production of a detailed and objective assessment of the total capacities of their children, will become personally interested in the problems of health, adaptation, and growth.

This book will be read with profit by medical officers of schools and by all those interested in education. It is a valuable and important work, capable of throwing new light on the study of growing boys.

A FRENCH COURSE OF HYGIENE.

Cours d'hygiène professé à l'Institut d'Hygiène de la Faculté de Médicine de Paris. Sous la direction de LÉON BERNARD et ROBERT DEBRÉ. Paris: Masson et Cie. 1927. Illustrated. In two volumes, pp. 1247 and 811. Fr.160.

In 1905 the late Prof. Jules Courmont organised advanced instruction in public health at the Faculty of Medicine at Lyons, and in 1921 similar teaching was instituted by the medical faculty of Paris, at the same time as a Diploma of Hygiene. These two volumes represent the substance of lectures given by some 38 specialists; the names best known in this country are those of E. Brumpt (Typhus and Yellow Fevers); E. Dujardin-Beaumetz, Chef de Service à l'Institut Pasteur (Plague); R. Sabouraud (Ringworm); Henri Pottevin (International Prophylaxis and International Sanitary Conventions); E. Sacquépée, Médecin Inspecteur de l'Armée (Food Poisoning); H. Vallée, Directeur du Laboratoire de Recherches au Ministère de l'Agriculture (Anthrax); and E. Rolants, Chef de Service à l'Institut Pasteur de Lille (Sewage and Trade Wastes). We may mention that Dr. Jules Renault, Conseiller Technique Sanitaire du Ministère de l'Hygiène, deals with the Sanitary Defence of (Land) Frontiers; whilst of the two editors, Dr. Léon Bernard, who is Professeur à la Faculté de Paris, writes most of the text on Tuberculosis, and Dr. Robert Debré, Professeur agrégé in the same Faculty, is responsible for the sections on Typhoid and Paratyphoid Fevers, Measles, Scarlet Fever, Mumps and Whooping-cough, Smallpox and Vaccination, Poliomyelitis and Encephalitis, and the Prevention of Tuberculosis in Infancy.

The editors have succeeded decidedly in presenting the work in an interesting form, and have almost entirely done away with repetitions. One of the noteworthy features is the relatively large contribution made by the veterinary profession. The article on Milk is by Henri Labbé, who also writes on Flour and Bread, Beverages, and in addition, Air and Atmosphere. Wine is fully considered, and the sections on food generally are comprehensive and contain valuable instruction. Rabies is dealt with by Cruveilhier in a special chapter, whilst glanders receives attention only in the general chapter by C. Dopter, Médicin Inspecteur de l'Armée, on the Rôle of Animals in the Transmission of Disease; the eradication of tuberculosis among cattle is somewhat scantily treated. The name of Prof. Léon Bernard on the title page ensures, however, that Tuberculosis in human beings is dealt with fully, and the section on Venereal Disease is admirably written by H. Gougerot. He advocates *le consultation à deux degrés*—i.e., the hospital patient sees the general physician or surgeon and then is passed on to the venereal diseases specialist working in an adjoining room. He also insists on the value of the general adoption of a system of prematrimonial certificates of health. Prostitution and the relative advantages of its regulation and abolition are discussed at considerable length, and this whole section is worthy of close study. Present-day tendencies in France are indicated by the emphasis laid on the protection of the mother and the social hygiene of the infant, a good deal of space being given to the feeding of babies. School hygiene receives but little mention, only about 18 pages being devoted to this important subject; cancer and its prevention takes up 14 pages. On the other hand there are 280 pages on occupational hygiene, and the section by Marcel Frois on the sanitation of workshops includes a chapter on the physiology of work devoted entirely to fatigue. Occupational poisonings are dealt with by M. Duvoir, whilst E. Kohn-Abrest, Director of the Paris Laboratory of Toxicology, writes especially on the laboratory side of this subject. Until French Governments remain longer in power it is hopeless to expect much French sanitary legislation, and A. Guillon, who deals with this topic, has a somewhat difficult task. An architect, Louis Feine, writes on "the hygiene of agglomeration," and

particularly on overcrowding in towns. "Hygiene and agglomeration," he says, are words which swear at finding themselves next to one another.

In the section on sewage, the antiquated septic tank figures largely. E. Rolants writes fully on activated sludge, and includes illustrations of installations at Manchester showing air being blown into the sewage; he is able to give figures of a French installation (at Mesly) of the Sheffield type, in which the air is beaten in with paddles.

Much of the text has a general message to all sanitarians, and the book should be read with interest by public health workers in other countries besides France.

AIDS TO GYNÆCOLOGY.

Seventh edition. By RICHARD E. TOTTENHAM, B.A., M.D., D.P.H. Dub., F.R.C.P.I. London: Baillière, Tindall and Cox. 1927. Pp. 132. 3*s*.

TEACHERS are inclined to look askance at books such as this, though it cannot be questioned that there is a type of student that finds them useful in revising his work just before an examination. Books of this kind must, therefore, be judged solely as to how far they meet the needs of those for whom they cater. It goes without saying that the matter in them must be sound, even though appraised on an examination rather than a clinical valuation. Prominence should be given to general principles and details left to be filled in by what has been learnt elsewhere, and the orderly arrangement of the subject should be such as in itself to be educative. Estimated by these criteria a word of praise may be given to the general soundness of the teaching, subject as it is to a compression that allows of no latitude in description. The modern views on the physiology of menstruation are briefly set out, almost a couple of pages are devoted to Sampson's work on endometrioma and tarry ovarian cysts, and, save in some minor points, a fair summary of gynæcological practice is given. Its weakness lies rather in the faulty arrangement by which the subject is largely comprised in a series of chapters on the regional affections of the genital tract from the vulva up to the ovaries and pelvic peritoneum. The book would have been far more instructive to the student had it been arranged on a pathological basis, growths and infections, for instance, being first discussed generally as they affect the reproductive tract, and then in particular as they involve each anatomical portion. We suggest to the author at his next revision to lay-out of his subject matter on lines that would give the maximum of education to the student in the minimum of space.

DIET AND DISEASE.

By CECIL WEBB-JOHNSON, M.B., Ch.B., Major R.A.M.C. (T.F.). London: Selwyn and Blount, Ltd. 1928. Pp. 157. 3*s*. 6*d*.

Dr. Webb-Johnson takes a high hand with his professional colleagues when he states that "the average medical man is almost totally ignorant of the parts which various foods play in keeping the body sound and fit." His book is an attempt to remedy this state of affairs. Chapters are given to each of the following: dyspepsia, obesity, teeth, nerves, constipation, rheumatism, gout, neuritis, blood pressure, liver, anæmia, cancer, depression, heart, insomnia, and old age. Suitable diets are indicated and directions given as to treatment on general lines, apart from drug therapy. The chapters on constipation and obesity are perhaps the most successful of the series, the author insisting strongly on the value and use of diet in these two conditions and stating his case clearly and succinctly. His advocacy of castor oil in constipation, should an aperient become necessary, and his omission to mention the paraffin series will not meet with general approval. At times he states opinions too briefly and without sufficient qualification. The following dicta cannot be accepted as written. "If the diet . . . is strictly adhered to there is no reason why diabetes should not be completely cured, or, in the gravest cases, held in check" (p. 45); in anæmia "the treatment is almost wholly dietetic" (p. 106); "eat wisely, live cleanly—keep the bowels open in a normal manner, and the dreadful scourge of cancer will pass you by" (p. 117). Such remarks can only lead to worry for the doctor and disappointment for the patient.

The book is written throughout in a common-sense way and contains much of value. It may be useful to the busy practitioner who has to construct a diet quickly and on general lines, but the assumption that most of the teaching may be novel to doctors is unsound. The work is well printed and produced.

PERNICIOUS ANÆMIA.

By S. CORNELL, M.B. Tor., Fellow in Duke University. North Carolina: Duke University Press. 1927. Pp. 311. 20*s*.

To all those interested in pernicious anæmia Dr. Cornell's book will prove extremely useful, for it contains a bibliography dealing with over 800 references in the literature, and every chapter of his work contains full indications as to the main source of further information on the abstruser points. His book is, therefore, of primary importance as a work of reference, and it is difficult to find a single point neglected regarding pernicious anæmia. It is this very completeness in the outline that may lead the unwary to infer, on the strength of isolated description of single cases, that various writers in the early decades of the last century anticipated the discovery of Addison. It will also be found that the author has hardly given sufficient details of the actual technique of certain microscopic processes for his book to be of practical value to those actually carrying out the laboratory investigations necessary in cases of pernicious anæmia. This omission is, however, of comparatively small importance, owing to the excellence of the reference system already alluded to. The book has been published at a time when liver extracts are only just engaging general interest, and it is only on the last page of the text that reference is made to them. Their significance, however, and information contained in recent preliminary reports are sufficient to render portions of the author's last chapter already out of date, for if extracts which contain neither protein nor iron are as effective as they appear to be, the references to diets containing large quantities of "food iron" become irrelevant. In view, however, of the present concentration on the problems of pernicious anæmia, Dr. Cornell's thoroughly documented volume is welcome.

ARTIFICIAL SUNLIGHT THERAPY.

Artificial Sunlight and Its Therapeutic Uses, Fourth edition. By FRANCIS HOWARD HUMPHRIS. M.D. Brux., F.R.C.P. Edin., Hon. Consulting X Ray Physician to the American Hospital in London and to Christ's Hospital. London: Humphrey Milford, Oxford University Press. 1928. Pp. 306+xx. 10*s*. 6*d*.

THIS book has been recognised by practitioners as of practical service to them, seeing that a fourth edition appears so soon after the original publication. The use of sunlight in many pathological conditions has resulted so satisfactorily as to stimulate a great deal of research in actinotherapy, and Dr. Humphris covers the field briefly, his notes on the production and use of artificial sunlight supplying a comprehensive account of the subject. We remain a little sceptical in regard to certain theories which the author holds as accounting for the essential processes set going by ultra-violet radiation, but his work is directed to meet the clinical requirements of his

public rather than to evoke biophysical arguments; it is—in his own words—"an attempt to put in a handy form and simple language the main conclusions that have been arrived at experimentally and clinically by authoritative research workers."

The four years which have elapsed since the first issue have seen a more general employment of actinotherapy, as new purposes have been found for its use, and this popularity of the treatment has brought in its train the peril of an indiscriminate use of artificial sunlight by operators imperfectly acquainted with its properties and with the dangers that may attend clinical administration. In this edition will be found fuller details of dosage and further refinements of technique, while special attention may be called to the chapter on the red and infra-red rays. The practitioner to-day must have a basis of general knowledge of actinotherapy, and this is what Dr. Humphris's manual succeeds in supplying.

THE LAW OF MONEYLENDING.

By LINTON THORP, LL.B., and A. AIKEN WATSON. London: Effingham Wilson. 1928. Pp. 133. 4*s*. 6*d*.

THE important committee which examined the need of amending the law of moneylending a year or two ago was told by a well-known City solicitor that doctors were frequently the victims of moneylenders. If this be so, the medical profession had better inform itself of the recent changes in the law, the extended powers of reopening harsh transactions, and the increased severity of the conditions imposed upon the moneylender in the carrying on of his trade. The two statutes (of 1900 and 1927) and the rules thereunder are sensibly set out and explained in the little book opportunely presented by Messrs. Linton Thorp and Aiken Watson. Unless the reader is mathematically minded, he may, in spite of all their help, be puzzled to understand the system for calculating interest (under the Schedule to the 1927 Act) in cases where the interest charged on a loan is not expressed in terms of a rate. And no text-book can definitely explain what moneylending bargains will be deemed "harsh and unconscionable"; the cases depend upon their own particular circumstances, though the 1927 Act says that interest exceeding the rate of 48 per cent. is to be deemed excessive unless the contrary be proved. It should be added that the 1927 Act, which does so much to clip the moneylenders' claws, does not apply to Northern Ireland; it is to be hoped that the Belfast Parliament will enact similar legislation soon.

JOURNALS.

AMERICAN REVIEW OF TUBERCULOSIS.—The issue of January, 1928, contains an article by Dr. Maurice Fishberg on infraclavicular tuberculous infiltrations. In his opinion true "apical" tuberculosis is relatively a benign form of the disease, such lesions being usually limited in extent and tending to heal spontaneously. Thus a progressive involvement of the lung leading ultimately to a fatal result is rare. "These patients," he remarks, "are treated for tuberculosis very successfully; they are the preferred class of 'incipients' . . . said to be the most suitable for Sanatorium Treatment." In sharp contrast with the cases of this type are those in which the initial lesions appear in the region of the lung just below the clavicle. Here there is, as a rule, no tendency to fibrosis and limitation. In this situation exudation is followed by areas of caseous broncho-pneumonia and cavitation. Such lesions may give rise to few symptoms in their early stages, though tubercle bacilli can usually be demonstrated in the sputum. A skiagram is essential if the site of the diseased area is to be located and its extent defined. A typical skiagram reveals soft homogeneous shadows below the clavicle, and often situated in the outer zone of the lung shadow. Cavities may occur in the same area although physical signs of this condition are absent. The appearance of a heavy shadow passing horizontally outwards below the clavicle may simulate an interlobar effusion, but has a sinister significance if due to tuberculous infiltration. Severe constitutional symptoms are usually associated with this condition, and physical signs are obvious. Nearly all Dr. Fishberg's cases yielded evidence of earlier tuberculous involvement, nor does he consider that these cases should be regarded as primary infections. Whether they are the result of exogenous or endogenous reinfection is often doubtful, but the latter is in his opinion the rule. Though the prognosis of infraclavicular infiltrations is grave, involution is possible, even after cavity formation has occurred. He points out, however, that some of the soft shadows seen may be the result of perifocal inflammation around a comparatively small tuberculous lesion. In such cases resolution of a simple exudation may simulate that of tuberculous deposit.—The same issue includes articles by Drs. Kennon Dunham and A. P. Derby on the physical signs over cavity in pulmonary tuberculosis. The bronchoscopic and surgical treatment of pulmonary suppuration is discussed by Dr. Evarts Graham. A paper is contributed by Dr. H. C. Sweeny on the granules of the tubercle bacillus. As the result of experiments in the culture of tubercle bacilli under various conditions he concludes that the granules in certain stages of their life cycle may reproduce either acid-fast micro-organisms or non-acid-fast bacilli, which are actively mobile. Other granules give rise to coccoid forms, while others, after passing through a gonidiform stage, may give rise under suitable conditions to pure cultures of tubercle bacilli.

INDIAN JOURNAL OF MEDICAL RESEARCH. Vol. XV. No. 3. January, 1928.—This full number of the journal contains some 20 original contributions, many of which are continuation reports of work recorded in previous numbers. S. S. Sokhey, S. K. Gokhale, M. A. Malandkar, and H. S. Billimoria, working at the Haffkine Institute, Bombay, have investigated hepatic functions in sprue, the net result of their inquiries going to show that in this disease the liver is not enough affected to show impairment by functional tests.—R. N. Chopra and C. A. Das Gupta have found that intravenous injections of antimony compounds had a provocative action in three cases of kala-azar in which the fibrotic changes in the liver and spleen were not too advanced.—R. N. Chopra, J. C. David, and B. B. Dikshit, in a comparative study of the action of cinchona alkaloids, have shown that these derivatives exert in varying degrees a stimulating effect on the uterus of the cat.—K. C. Sen and S. K. Basu have studied the hæmolysis of red blood corpuscles by bile-salts, and the inhibiting action of normal serum and egg albumin with reference to the permeability change of the stroma.—Major J. A. Sinton continues his notes on some Indian species of the genus phlebotomus, and together with Major W. Bird and Assistant Surgeon S. N. Eate, his studies on the oral administration of quinine-stovarsol in malaria.—J. A. Manifold and A. J. De Monte contribute an important report upon dysentery and diarrhœa in Poona, which was due to a Flexner infection.—T. C. Boyd and A. C. Roy contribute notes on the cholesterol content of Indian blood in health and in leprosy.—Part XXIII. of the Revision of the Culicine Mosquitoes of India is by P. J. Barraud and, together with G. Covell, he has studied the morphology of the buccal cavity of anopheline and culicine mosquitoes.—S. D. S. Greval has compared the Kahn, Micro-kahn and Wassermann reactions in leprosy.—Asa C. Chandler has completed his studies on the prevalence and epidemiology of hookworm and other helminthic infections in India.—T. C. McCombie Young and J. D. Baily publish an extensive study of malaria in Coorg.—R. McCarrison has two articles, on lathyrism and on the experimental production of stone in the bladder respectively.—H. E. Shortt and C. S. Swaminath discuss the method of feeding of *Phlebotomus argentipes* in its bearing on the transmission of kala-azar.

THE LANCET.

LONDON: SATURDAY, APRIL 7, 1928.

EPILEPSY.

THERE seems to have been in the last few years a revival of interest in the subject of epilepsy. This is probably, to a considerable extent, due to the development of biochemistry, which has offered lines of investigation of an entirely new order, but the influence has been felt also in many methods of approach with which biochemistry is little concerned. Dr. JAMES COLLIER has given a stimulating review of the whole subject in the Lumleian lectures, of which we publish this week the concluding instalment. The first impression which his presentation conveys to the mind of the reader is that a baffling problem is presented by almost every fact associated with the disease and that on almost every point the most diverse views are held. It follows, too, as Dr. COLLIER has hinted, that there must, of necessity, be a large personal element in the conception of this disease and personal views must be reflected in any discussion of it. So far as idiopathic epilepsy is concerned, no pathological changes have been found upon which any hypothesis as to the nature of epilepsy can be built up, and attention has therefore turned to the possibility of finding an explanation of the disease in some perversion of the chemistry of life—some "metabolic dyscrasia" which may lead to the presence within the body of substances acting upon the nervous system in much the same manner as do the convulsant poisons. PAGNIEZ, MOUZON, and TURPIN found that when serum taken from epileptic patients at the time of an attack was injected into the heart or into the carotid artery of animals a series of convulsions occurred; this effect was produced only by the serum taken from the patients when an attack was about to occur, and no such effect was produced by the serum of other subjects. These experiments suggest very strongly that the determining agent for the epileptic attack is present in the blood when the attack is about to occur. Dr. COLLIER points also to certain clinical features of epilepsy as arguments in favour of a metabolic disturbance being the essential cause of the disease—its incidence in early infancy, particularly in association with rickets, its periodicity in certain cases, the way in which it is influenced by pregnancy, and, finally, the occurrence of status epilepticus. Clinically, status epilepticus is closely akin to the convulsions of uræmia and of eclampsia; furthermore, in the fatal cases, intense fatty degeneration of the cardiac muscle is found after death, and this is probably the result of an acute toxæmia. In this connexion the lecturer calls attention to a terminal epileptic coma, which is status epilepticus without the convulsions, and is comparable to uræmic coma.

Dr. COLLIER applies the hypothesis of a metabolic dyscrasia also to those cases in which convulsions occur in association with organic lesions of the brain. It is well known that only a small proportion of cases of cerebral injury or organic cerebral disease present convulsive phenomena, and the necessity of postulating a second determining factor has many times been pointed out. Other writers have supposed the second factor to be an hereditary epileptic tendency, and there is no contradiction between the two views. What is important is that the need of such a second factor should be recognised. DANDY and ELMAN, working at the Johns Hopkins Institute, found that in cats, which had a lesion of the brain, convulsions could be brought on by one-third to one-seventh of the dose of wormwood oil which was required to excite such attacks in normal animals, and also that a minimal convulsive dose produced unilateral convulsion corresponding to the side of the brain injured. These results indicate that a local lesion of the brain, not in itself epileptogenous, in conjunction with a second disturbing factor, which is also not in itself epileptogenous, can produce both local and general convulsions. Dr. COLLIER'S explanation that local cerebral disease in conjunction with a metabolic dyscrasia may account for the convulsions of organic cerebral disease is similar. His second lecture was devoted to "the borderland of epilepsy"—migraine, narcolepsy, pyknolepsy, vaso-vagal attacks, and tetany—and in seeking to bring all these paroxysmal maladies under the same heading as epilepsy Dr. COLLIER rather cuts across the recent trend in this country; but it is undoubtedly useful that their relationship to the graver symptom-complex should be kept in view. Migraine is widely regarded as dependent upon a metabolic dyscrasia. Its symptoms may be divided into two groups: (1) the hallucinations, paralyses, and abnormal mental states; and (2) the headache and vomiting. Those of the first group resemble symptoms of epilepsy, except for the facts that they last longer and are not accompanied by a convulsion, while those of the second group have their counterpart in the headache and vomiting which often follow the epileptic attack. Narcolepsy and pyknolepsy Dr. COLLIER does not admit as individual disease-entities, but considers that many cases of these groups show some typical feature which brands them as cases of epilepsy and that there is no line of demarcation. Vaso-vagal attacks, however, he regards as distinct, though belonging to the same clinical and pathological group. These attacks, of which little has been written in recent years, have the characters of a long-drawn-out petit mal attack; "the aura, the pallor, and the semi-consciousness last minutes or hours instead of fractions of a second," whereas "velocity is an essential element in the attack of ordinary epilepsy." Syncopal attacks, similarly, are not epileptic, but are to be classed in the same group, and Dr. COLLIER believes that the clinical distinctions between the syncopal and the epileptic are not absolute.

The site of origin in the nervous system and the nature of the epileptic processes receive consideration in the final lecture. The site of origin of the disturbance is definitely referred to the cerebral cortex, because it is when tumours are so situated as to affect the cortex that they are associated

with convulsions. But the view is taken that as a result of the disturbance of cortical function, positive and negative phenomena occur which have their pattern determined by the function of the lower levels of the nervous system. The most commonly occurring feature in all epileptic symptoms is loss of function—e.g., loss of consciousness, loss of speech—while the positive symptoms which occur, such as convulsive movement and sensations of vision or of taste or smell, are elementary crude phenomena which do not seem to belong to the highest levels of the nervous system. By reason of these considerations Dr. COLLIER adheres to the hypothesis of HARTENBERG that the essential element in the epileptic attack is a sudden loss of function in the higher levels of the nervous system, and that all the positive phenomena which occur have their origin in lower centres. This, of course, is very different from the orthodox teaching of "cortical excitation," from which there appears now to be a reversion, but the fact that many neurologists still hold to the traditional view shows what diversity of opinion may prevail on points that appear to be among the more soluble in this difficult disease.

WOMEN'S WORK DURING THE MENSTRUAL PERIOD.

THANKS largely to the enthusiasm and patient researches of Dr. ALICE CLOW, Prof. WINIFRED CULLIS, and other women investigators, the Victorian attitude to menstruation has gone for good. Everybody knows now that women are not necessarily "unwell" once a month, and the invasion of every kind of industry by women workers has in itself been a massive experiment proving that the period does not mean any noticeable degree of invalidism for the great majority. With the introduction of applied psychology, and the tests of accuracy and speed perfected by workers in that field, came the opportunity for unimpeachable scientific proof of the degree of disability, if any, imposed by the process of menstruation. Prof. CULLIS and Dr. CLOW[1] made inquiry into the subjective condition of their material and into certain physiological phenomena, such as the temperature and pulse-rate. Dr. HOLLINGWORTH,[2] in the United States, went further and set certain definite tests, concluding that the menstrual cycle has no effect on the mental and muscular efficiency of normal women. The criticism to be levelled against her work is that all her 23 subjects were of the same class — namely, university graduates—and only six of them were studied intensively. Moreover, they all knew the purpose of the experiments, and their natural desire to prove that their sex suffered from no disability may have called forth some unsuspected effort. Miss S. C. M. SOWTON,[3] under the supervision of Dr. C. S. MYERS, has just published the results of a careful investigation into the influence of normal menstruation in a more representative sample, including 13 university students and 16 factory operatives.

The inquiry included a simple number-checking test, a spearing test, and McDougall's dotting test. The difficulty of keeping the subject unaware of the purpose of the inquiry was ingeniously overcome by asking her to note a number of factors, such as the state of the bowels and the degree of fatigue or excitement. Among the list of 17 factors the presence or absence of the monthly period attracted no especial attention. This record also served to bring out the tremendous importance of psychological factors in improving or impairing efficiency. In fact, it was found best in the end to study each subject's performance separately and in detail. The results of the tests were carefully plotted and some of them were submitted to a thorough statistical analysis. Efficiency at the spearing test proved to be largely a matter of manual skill, and to show itself in girls who were good at games and had a lively sense of rhythm. The number-checking was more useful, calling for quickness of eye and hand combined with concentration and memory. Included in the same report is the result of an investigation by Miss E. M. BEDALE on a number of physiological conditions during the menstrual cycle, in an attempt to throw light on the vexed question of the alleged periodic rhythm of a woman's physiology. It embodies a three month's study of one woman under closely controlled conditions of diet, exercise, and daily work. In this case the subject knew the aim of the experiment, but claimed to have only an academic interest in the result, while the observer did not know it, nor did she know when the periods were on.

The results of the efficiency test laid stress on social status as an important factor. Five students and one workgirl only were uninfluenced by menstruation. Two students and two workgirls gave a better performance when menstruating than at other times; these were rather highly strung, healthy girls, and the result seems to be due to increased excitability or the liberation of reserve forces. Nine girls showed reduced efficiency during or just before the period, and when unsatisfactory cases had been excluded, the remaining five were all factory employees. No correlation was found between the subjective record of feeling fit or unfit, and the degree of efficiency revealed by the tests. It was found that the lowering of efficiency was never greater than that which might occur from other reasons between the periods. There was some indication of influence at the middle of the inter-menstrual period and still more in the pre-menstrual week. This corresponds with Miss BEDALE'S conclusion that there is a reduction of functional activity shortly before menstruation, while a general heightening occurs late in the inter-menstrual phase. Temperature, basal metabolism, vital capacity, respiration- and pulse-rates, blood pressure and capacity for work, all showed this increased activity; the records of the basal pulse-rate and basal blood pressure were, however, inconclusive. This variation is not more than 5 per cent. below and above normal, and Miss BEDALE therefore agrees with her colleagues that there is no reason to think that the fundamental physiological rhythm of a woman affects considerably or constantly the quantity or quality of her work. The combined results of the two investigations should go far to convince the public mind that menstruation has, as a rule, no noticeable effect on working capacity among normal healthy women. That there are women who find their monthly periods a more or less heavy burden no one will deny, and the individual variations are clearly shown by the report. The point for employers and doctors to remember is, that an appreciable lowering of efficiency is to be regarded not as normal and inevitable, but as pathological and calling for special consideration.

TONSILLECTOMY AND RHEUMATISM.

IN view of the serious nature of the problem of rheumatic heart disease and its control, any study of ætiological factors or methods of prevention must evoke interest. Dr. A. D. KAISER, of Rochester, N.Y., has attempted [1] an evaluation of tonsillectomy in these conditions. Opinions as to the influence of the tonsils on various rheumatic symptoms are still conflicting, and since this is, in part, as in other problems, the direct result of paucity of data, an examination of the histories of 48,000 school-children raises a pleasant feeling of expectation. The two problems are, first, whether enucleation of the tonsils will safeguard the child against rheumatic fever, chorea, and heart disease if these infections are not already present; and, secondly, if they are or have been present, whether tonsillectomy beneficially influences the end-results or offers any assurance that recurrence can be prevented? To investigate these problems a large group of children in whom the tonsils have been removed must be subjected to a fairly long period of observation, together with a control sample of children of similar age and under similar environmental conditions. The vital statistics of the two groups, assuming the numbers to be sufficiently large, as they are in this study, will provide an answer to both propositions. It is a pity that the present study discloses no serious attempt to assess the value of the so-called control series. The author has simply taken for granted that the group is in all essential respects similar to the operated group. The only results which may be of any value seem to confuse two distinct issues. The first table in the paper gives the incidence rates of rheumatic fever, growing pains, chorea, carditis, and scarlet fever upon the two groups of children, those who had and those who had not been subjected to operation, but with no distinction as to whether these attacks occurred before or after the commencement of the inquiry. Taking the results as they stand, however, and remembering that many of the tonsillectomised children were in all probability operated on for some rheumatic condition (when, cæteris paribus, the incidence should be higher in that group than in the controls), it is of interest to note that all the above-mentioned conditions have a lower incidence in the tonsillectomised than in the non-tonsillectomised children. Even this observation, however, loses some of its importance when we examine the nature of the control series adopted. This consisted of a group of children for whom tonsillectomy was advised, but which "for various reasons was not performed." A grouping of the rheumatic manifestations, as obtained from the parents' history, shows that, in the 48,000 children, those who were operated on had an incidence rate of 8 per cent., whereas in the group in which operation was not performed the incidence was 10 per cent. There is no justification, in this or any other finding in the paper, for the statement that, "It is fair to conclude that the tonsils undoubtedly are a focus in many cases of rheumatic fever. Their removal offers considerable protection against recurrent attacks, and when the tonsils are removed before symptoms have developed, the chances for escaping rheumatic infection are appreciably increased."

In our own columns last week Dr. K. D. WILKINSON and Dr. A. G. OGILVIE gave the results of an analysis which attempts to answer the most difficult of the problems involved—namely, the effect of removal of the tonsils in the course of the disease on the end-results. Translating the findings of such a study into compact statistics involves several difficulties, mentioned (but perhaps hardly sufficiently emphasised) by the authors. In the first place, the inability to trace all patients who had come under treatment may, depending on the reasons for inability to trace, amount in certain instances to unavoidable selection, and since a large proportion of the total cases in this study could not be followed up, some weight should be given to this objection. In a comparison of two methods of treatment, for example, cases untraced owing to death are most likely to lead to biased results, since more of the patients subjected to a less efficient method will probably be lost from this cause. A definite bias, tending to produce equality in the results of treatment by two methods where no such equality exists, may thus be introduced. There is, again, the question of the adequacy of the control series. As in this study, where the problem is to determine the effect of an operative procedure (however simple) carried out while the disease is still active, it is extremely difficult to satisfy the critical of the adequacy of the series used for comparative purposes. Operation may be contra-indicated in unusually severe cases or by the appearance of complications, so that in the non-operated group remains an undue proportion of cases in which the course of the disease was of more than average severity. Even in the present series of cases this disturbing influence cannot wholly be disregarded, since it is stated that tonsillectomy is performed as early as possible "even in the presence of acute chorea or with symptoms of severe rheumatic infection, provided that signs of heart failure are absent." The group in which operation was not performed might well, therefore, form an unfair sample of the total cases. These objections may prove to be theoretical, but are worth bearing in mind when the number of cases studied is rather small. In spite of the small size of their sample, the authors' results are very definite and indicate that a significantly greater proportion of children who have suffered from rheumatic fever or chorea recover without cardiac disability when tonsillectomy has been performed. We may hope that further studies on larger numbers will be forthcoming.

[1] Amer. Med. Assoc., 1927, lxxxix., 2239.

THE annual congress of the Royal Sanitary Institute will be held at Plymouth from July 16th–21st under the presidency of Lord Astor. There will be the usual sectional meetings for the reading and discussion of papers relating to Preventive Medicine, Engineering and Architecture, Maternity and Child Welfare, including School Hygiene, Personal and Domestic Hygiene, Hygiene of Food, Hygiene in Industry, and Veterinary Hygiene. Conferences of various groups of public health officers have been planned and a popular lecture will be given by Prof. W. E. Dixon, F.R.S. During the congress a health exhibition illustrating municipal and domestic hygiene, appliances for houses and general sanitation, and the promotion of physical welfare has been arranged. A large number of delegates have already been appointed and representatives from foreign countries and parts of the British Empire will be attending. The Ministry of Health and corresponding authorities in Scotland and Ireland are ready to consider applications from local authorities for the payment of expenses of delegates, and the railway companies are issuing cheap tickets. Particulars of the programme may be had from the Secretary of the Institute at 90, Buckingham Palace-road, London, S.W.1.

Annotations.

"Ne quid nimis."

"AVIATION SICKNESS."

IN the latest instalment of little monographs on industrial hygiene from the International Labour Office (Occupation and Health Series, No. 86) is a rather alarming account of what is entitled aviation or aviators' sickness. This is a train of complex symptoms occurring in those who take the air and leading on to a state of physical and mental strain. The writer of the monograph admits, however, that the view he takes of this syndrome is not universally held, and that there are others who fail to differentiate it in any essential way from similar symptoms which may occur apart from flying. This is certainly true as regards our own Royal Air Force, for symptoms such as those described do not occur with any frequency, if at all, among its trained members. The fact is that the monograph is really a synopsis of books and reports published between 1917 and 1926, many of them at a date when selection of pilots was not so careful as it is to-day. Some of the information is misleading, as when we are informed that gastro-intestinal atony is considered a contra-indication to admission to the Royal Air Force because brusque displacements of the aeroplane are capable of inflicting injury on the abdominal organs and so giving rise to fatal syncope. The fact being that a flabby abdominal wall is unpopular in the R.A.F. because it is associated with splanchnic pooling and consequent circulatory insufficiency. We are also told that in the R.A.F. the psychomotor reactions to various stimuli are exactly determined, whereas it has been shown after careful inquiry that these reactions do not afford any real indication of fitness for piloting duties. Nor is the sense of equilibration now determined by routine turning tests, war experience having proved that the Bárány tests afford no true information as to a candidate's potential flying aptitude.

Although, therefore, the monograph cannot be taken as a guide to "aviators' sickness" in this country, nevertheless it contains points of interest to the air medical officer. Dealing with "descent sickness," it is stated "pilots may be seized with emotional disturbance from which even the strongest may not be exempt; a feeling of emptiness, thoughts and visions of death conjured up by the rapidity of the fall (60, 90, 150 km. per hour)." This is no doubt a possible experience, although it suggests unsuitable personnel; the trained airman does not suffer from a disagreeable feeling of falling the moment the aeroplane commences to point downwards. What follows may be taken as an account of imperfect adaptation. On commencing to fall, breathing stops, but then regains its rhythm, the heart quickens and palpitation increases. The aviator has a sense of constriction, sometimes slight, but capable of feeling like a burn. Hearing becomes difficult; the feelings of fullness and auricular tension reappear, followed by "buzzing salvoes or hammerings, neuralgias, tearing pains, acute pricking sensations, intolerable pains unaffected by swallowing, &c." These sensations, which last during the whole descent, seem even to become more intense after landing. Then, also, there may be incoördination with markedly uncertain movements, a whim to jump out of the machine. Marked circulatory disturbance apparently exists, with many other symptoms which diminish in the following 12 to 24 hours. It is little wonder that aviators' asthenia or sickness should supervene on these symptoms as well as psychical fatigue leading to "aviators' neurosis," which is also described in considerable detail. Various theories are held to account for this sickness—e.g., anoxæmia due to the lowered partial pressure of oxygen, acapnia from washing out of carbon dioxide, distension of intestinal gases pushing up the diaphragm and interfering with respiration. "Descent sickness" is attributed partly to tubal insufficiency causing inadequate equalisation of pressure within the middle ear and partly to abnormal excitation of the vestibular apparatus, which cause changes in the circulatory pressures. Great cold may play a part in inducing general fatigue, while cardiac fatigue may result from constant adaptation to variations of pressure. Some authorities believe that a slight renal auto-intoxication induces the first stage of sickness, which leads on to an asthenia due to renal insufficiency. In his recent series of lectures at the Royal Institution, Group-Captain Martin Flack dealt with the problems of high flying. He showed that the chief reason for the administration of oxygen to flying personnel lies in the fact that the symptoms experienced at high altitudes may in the main be attributed to oxygen-want. Diminution of atmospheric pressure per se produces no mechanical effects, since the altered pressure is transmitted equally in all directions through the semi-fluid body tissues. It has been suggested, however, that the airman may be liable to symptoms akin to those experienced by the diver or the worker in compressed air when the pressure is released too suddenly. But in the case of the airman the diminution in pressure is not yet sufficiently great or rapid to bring about any liberation of gases held in the blood plasma. By breathing oxygen from the start of the experiment, it has, in fact, been possible in a rarefaction chamber to attain a condition corresponding to an altitude of 43,800 ft. without any ill-effect whatever. Such ill-effects of diminished pressure as do occur are due to the action upon gases which are, so to speak, enclosed by the body—e.g., within the air spaces of the nose, and particularly in the Eustachian tubes. The diminution of pressure also affects the alimentary tract. Any gases present in the intestines will distend the abdomen and push up the diaphragm; but as the amount of gas is normally not large, and its expansion induces peristalsis, it is soon voided from the body. Inconveniences from this cause are rare in practice. The effect of the great cold of high altitudes is to throw added strain upon the respiratory and circulatory mechanisms as well as to induce numbness and sensations of fatigue.

Generally speaking, said Group-Captain Flack, airmen's breakdown may be classed as due to fatigue or asthenia. Flying does impose a very definite stress upon the body, especially when flights are made without the aid of oxygen for long periods at relatively high altitudes. When to this is added the stress of offensive and defensive warfare in the air, it is obvious that bodily strain or breakdown is likely to ensue if the stress be too prolonged. But the signs and symptoms of "flying strain" are varied and are such as might occur in an individual quite apart from flying. In the past war it was found that flying strain presented manifestations such as a gradual loss of power to fly high, respiratory embarrassment, palpitation of the heart, persistent headaches and lassitude, and dizziness in the air. Generally speaking, fainting in the air and syncope were rare. Mental symptoms, usually in the form of an "anxiety neurosis," might or might not be present. In many cases it was difficult to say whether breakdown was to be attributed primarily to the effects of flying or to the nervous strain of air warfare, but such symptoms were frequently found to occur in those who had taken no part in active service in the air. In the Geneva monograph statistics of accidents are given which testify to the increasing safety of flying in relation to number of miles and hours flown. The recent British record for civilian flying—namely, 60,000 passengers carried and 3,000,000 miles flown in just over two years without serious accident speaks for itself.

THE HARVEY TERCENTENARY.

THE Royal College of Physicians of London is celebrating the tercentenary of Harvey's great publication from May 14th–18th. We have already set out[1] a provisional programme of arrangements, and we are asked to make it known that the College has reserved a proportion of tickets for such Members and Licentiates of the College as may wish to be present at certain parts of the celebrations. One hundred tickets are available for the conversazione at the Hall of the Merchant Taylors Company at 9 P.M. on Tuesday, May 15th; each ticket-holder is invited to bring a lady with him. A similar reservation for Members and Licentiates, without ladies, has been made for the banquet at the Guildhall at 7 P.M. on Wednesday, May 16th. There will be an inclusive charge of 2 guineas for each dinner ticket, which should be sent as soon as the applicant receives notice that a ticket has been allotted. Some tickets will also be allotted to Members and Licentiates for the demonstrations in the Physiological Department of University College, Gower-street, on Tuesday and Wednesday mornings, 10.30 to 12.30, at which, along with demonstrations of recent additions to our knowledge of the circulation, will be shown a film specially prepared for the occasion by the College, displaying a reproduction of Harvey's original experiments. Members and Licentiates are advised to make early application, as tickets will be allotted to both London and provincial applicants as far as practicable in the order of application. Letters should be addressed to the Registrar, Royal College of Physicians, Pall Mall East, London, S.W.1.

SEASONAL VARIATIONS IN THE ANTIRACHITIC VALUE OF SUNLIGHT.

SINCE the existence of a dietetic antirachitic factor was demonstrated by Mellanby more than ten years ago the elucidation of the ætiology of rickets and of the photosynthesis of vitamin D has been the object of systematic research in all parts of the world. The rôle of sunlight in the production of vitamin D is now generally recognised, but the antirachitic value of light at different times of year and at different latitudes has only recently been studied. In an address recently delivered at Kansas City before the Inter-State Post-Graduate Medical Association, Dr. Alan Brown and Dr. F. F. Tisdall make a valuable contribution to our knowledge. After tracing briefly the steps in the investigation of the ætiology and specific cure of rickets, they emphasise the practical value of the available data, as illustrated by their own experiments on the value of sunlight in Toronto. The ultra-violet rays constitute only about 1 per cent. of the total solar radiation at the latitude of Toronto, and of these only a small band of rays (3130–2900 A.U.) are known to have antirachitic value. Since the wave-length 2900 A.U. is the shortest recorded under optimal conditions, it is obvious that for a great part of the year the antirachitic band is still further restricted; the more so as it is just this extreme region of the solar spectrum that is most readily absorbed by smoke and moisture in the atmosphere. After mentioning the important observations of Dorno on seasonal variations of sunlight in the high Alps, the authors proceed to describe their own experiments.

Rats fed on a rachitogenic diet were placed out of doors from 11 A.M. to 1 P.M. daily, control animals on the same diet being kept in the dark during the experimental period. Each week throughout the year batches of rats were started under these conditions, and after a month each batch was killed and examined for signs of rickets. The results showed that in Toronto even winter sunshine had slight antirachitic value, but from the end of February onwards this value increased sharply, corresponding with an increase in the shorter rays of the solar spectrum. It is worthy of note that the biological test bears very little relationship to meteorological records of sunshine during the corresponding periods, owing to the ease with which the effective rays are absorbed. A second series of experiments designed to test the relative values of direct sunshine and of "sky-shine" demonstrated that the scattered rays were from a half to two-thirds as effective as the direct sunshine, a point of practical importance as indicating a means of applying an efficient dose of ultra-violet rays in cases where radiant heat is undesirable. Animals exposed to light were not only protected from rickets, but also showed an increased resistance to deliberate infection, twice as many of the irradiated rats surviving an intraperitoneal injection of pathogenic bacteria as did controls kept in the dark. The intestinal contents of the irradiated rats were found to be more acid than those of the controls, indicating a better digestion in the former.

Tests carried out with various special glasses transparent to ultra-violet rays convinced the writers that for glazing ordinary windows they were of little value, owing to the small amount of sky-shine that is available. To be effective these glasses should be used in the construction of special solaria, where both direct and diffuse light can be made use of. Sunlight filtered through Corning glass, Vioray, and Vitaglass was shown to have from 25 per cent. to 50 per cent. of the antirachitic value of unfiltered sunlight. Drs. Brown and Tisdall conclude that special glass screens, of the type considered, are of value as a protection from the cold during exposure to the early spring sunshine in places with a climate like that of Toronto.

[1] THE LANCET, March 24th, 1928, p. 621.

THE G.M.C. AND INCOME-TAX.

THE claim of the General Medical Council to have its income exempted from tax, on the ground that it is a charity, has again failed. First the Special Commissioners decided against it, then Mr. Justice Rowlatt confirmed that decision last November, and now the Court of Appeal has agreed with him. The argument for the Council was briefly this: The preamble of the Medical Act says that it is expedient that persons requiring medical aid should be able to distinguish qualified from unqualified practitioners; it is the duty of the Council to keep a register of qualified practitioners and also to supervise medical studies and education as well as to edit and issue the British Pharmacopœia; these objects are of general public benefit; therefore the Council is a charity and entitled to income-tax exemption under Section 37 of the Income-Tax Act. Up to a certain point the Court of Appeal agreed. The Master of the Rolls said that the Council's objects and duties were all for the public benefit. Those objects and duties, however, are also of benefit to the medical profession. The public interest is served, but the professional interest is served also. Lord Hanworth asked himself if the Council was formed for the promotion of objects beneficial to the medical profession; he found himself obliged to answer in the affirmative and he also found himself unable to say that the Council's income was applicable, and had been applied, to charitable purposes only.

There are two previous decisions which illustrate the point. In the case of the Institute of Civil Engineers it was held that the main purpose of the body was the promotion of science. There might be some subsidiary purposes or objects, but the property of the institution, having to be applied and being applied for the purposes of the institution, was legally appropriated and applied for the promotion of science within the meaning of the income-tax law as it then stood. On the other hand, in 1886 the Society of Writers to the Signet in Scotland was held not to be exempt from tax because its objects were not substantially charitable; the body, it was said, was mainly one of several portals to a profession. Similarly the income of the Royal College of Surgeons of England was held liable to income-tax in 1899 because, though one of the objects of the Royal College was the promotion of the science of surgery, another (perhaps equally important) was the promotion of the interests of those practising

or about to practise surgery, including the examination of students and candidates for qualifications and honours. This second object was not charitable. After analysing the property of the Royal College to see how far its income could be regarded as applied to the first object only, the Court refused to exempt from tax the offices in Lincoln's Inn-fields, the examination hall, and even the libraries. It seems reasonable to say that, if the General Medical Council has been created by Parliament for the main purpose of supervising medical education and ensuring a supply of qualified practitioners, its other functions are ancillary and supplementary. But at present the law is committed to searching for signs of dualism—on the one hand the protection of the public, on the other the protection of the practitioner; while this practice prevails, it seems difficult to regard any professional organisation as, in the technical legal sense, a charity.

SILVER NITRATE IN THE EYE.

A CASE which illustrates the need for care in using silver nitrate to prevent ophthalmia is recorded by Dr. J. G. F. Heal in a recent number of the *British Journal of Ophthalmology*. As the mother was believed to have gonorrhœa, the doctor ordered nitrate of silver in a strength of 1·5 per cent. to be dropped into each eye three times a day, and at least five instillations had been done before Dr. Heal was called in. He found the child with conjunctival hæmorrhage and steamy cornea on both sides, and on one side the hæmorrhage proved so persistent that on the fourth day the infant had to be put under chloroform so that the bleeding-points could be touched with a cautery. Five weeks later the eyes were normal. As a prophylactic nitrate of silver drops should not be used in a strength greater than 1 per cent., and caution is needed where they are used more than once or twice.

KIENBOCK'S DISEASE.

Dr. F. W. Van Valkenburg,[1] who records an illustrative case, defines this condition as a chronic slowly progressive type of osteitis of the semilunar bone. The following three forms have been described by W. Müller, the classification being based on their ætiology: (1) an anatomical form due to abnormal pressure lines from anatomical abnormalities; (2) an occupational form due to repeated minimal trauma; and (3) a traumatic form due to a single violent injury. The patient's first complaint is that of a lame wrist which may or may not have been preceded by a history of trauma. The disease does not usually become well developed until after the lapse of six or eight months, when examination reveals definite tenderness over the semilunar bone, limitation of flexion, and extension of the wrist, and localisation of pain over the semilunar bone on tapping the head of the third metacarpal with the fist closed and the hand in ulnar adduction. The head of the third metacarpal will also be found to be on the same level as those of the second and fourth, whereas normally it is more prominent. X ray examination at an early stage is usually negative, but after seven to nine months the semilunar bone appears whiter and more dense, and later still shows fragmentation and atrophy. Kienbock's disease must be distinguished from tuberculosis, syphilis, and chronic arthritis of the wrist due to other causes. In the early stage conservative treatment in the form of immobilisation for one or two months with massage and electricity is indicated, but operation is required in long-standing cases and those in which conservative treatment has failed. In Dr. Van Valkenburg's case, which occurred in a man aged 39, a cabinet-maker by occupation, the condition developed without any history of injury to the wrist. The Wassermann reaction in the blood was negative. In spite of a wrist support the joint became much more painful and in the course of a few months X rays showed the typical appearances of Kienbock's disease. After the condition had lasted for six months without any improvement under conservative treatment the semilunar bone was removed under ether anæsthesia, after which steady improvement took place, the final result being that extension and flexion were approximately one-half that of the normal wrist.

[1] Minnesota Medicine, March, 1928.

A CORONER ON ANÆSTHETICS.

AT a recent inquest in the City Dr. F. J. Waldo remarked on the increasing number of cases coming before him in which death has occurred during the administration of ether, as opposed to his experience of the past in which chloroform figured much more largely in these fatalities. The first obvious fact in this connexion is, of course, that the use of ether has increased and that of chloroform has decreased enormously. Dr. Waldo cannot, we think, justly assume that the proportional death-rate of ether has risen while that of chloroform has fallen. Nor can his apparent deduction that the deaths under ether have been due to the use of an impure drug be accepted generally without fuller accounts of the cases and fuller skilled investigation of the facts. Impurity has been shown to be the probable source of the trouble in that particular kind of case characterised by convulsions, but we believe this symptom did not figure prominently in the fatalities recorded before the coroner. With Dr. Waldo's reiterated plea for research in connexion with anæsthetics and their administration we are in full accord, and we are happy to know that valuable work of the kind is going on under the joint committee set up by the Medical Research Council and the Section of Anæsthetics of the Royal Society of Medicine.

MAXIMA CHARTA.

Senator Copeland introduced into Congress last month a Bill which would give the same rights and privileges to the degree of doctor of osteopathy as to that of medicine. This information has to be set against other news from America, printed in another column, which suggests that chiropractic has suffered something of a set-back. According to the *Journal of the American Medical Association* the Copeland Bill is framed upon remarkably generous and comprehensive lines. It contains, for instance, a definition of drugless healing which is to cover "any system of healing that teaches that disease may be prevented, relieved, or cured without the use of drugs, medicine, or operative surgery." Any five or more adherents of any so-called drugless method of healing can present a petition (if the Bill should become law) demanding the appointment of an official and permanent board of examiners, and thereupon their particular cult will apparently be recognised as on an equal footing with the orthodox practice of medicine and surgery. The only limitation, we are told, upon the official recognition of any particular drugless cult is the requirement that the petitioners should somehow differentiate it from the unrestricted practice of the healing art. It is difficult to comment further upon Senator Copeland's proposals without a study of their exact text; but it is understood that they include the licensing of osteopaths to practise surgery and to prescribe drugs, the issuing of licences with reciprocal effect, and the general authorisation of diagnosis and treatment either by prayer or spiritual means, or by hygienic, dietetic, or domestic remedies without any insistence upon evidence of age, character, or professional ability. What may perhaps be described as freak legislation is by no means confined to America, but for the present the sheet-anchor of the qualified medical practitioner in this country—namely, Section 32 of the Medical Act of 1858—looks like holding fast. Statutory provisions for professional organisation are matters of slow growth among us. Midwives, nurses, and nursing homes are regulated under comparatively recent Acts of Parliament, but the Bills dealing with opticians and surveyors have made little progress and

the Bill for the professional regulation of architects (containing a discipline section which closely recalls Section 29 of the Medical Act) has been talked out in the past session to the prejudice of its prospects of becoming law. On the other hand, a Bill to tighten up the disciplinary control over the further employment of solicitors who have been struck off the rolls may perhaps make progress later in the year.

THE FOUNDLING SITE.

THE Foundling Hospital lies on a site of nine acres, surrounded by streets and squares from which its revenue is derived. Founded nearly 200 years ago by Captain Coram for the benefit of London children, it has proved a healthy home for many generations of orphans, whilst the district around has preserved a charm and beauty found in few parts of the metropolis. Its value both to mind and body is enhanced because it lies between desolate slums, and in the neighbourhood of no fewer than seven hospitals. When, therefore, in 1925 the 56 acres comprising the estate were sold to a syndicate and the Foundling institution was moved to the country, all those familiar with the district were anxious to preserve at least its open spaces. A protective association was organised and was able to secure a Parliamentary veto to a proposal to place Covent Garden market on the nine acres lying between Mecklenburg-square and Brunswick-square. When, later, the London County Council intervened and announced that it would prepare a town-planning scheme for this and neighbouring areas it was felt that the worst dangers were passed. This proved a delusion, for it is now discovered that the Council will permit the erection of a building 75 ft. high and 100 ft. deep along the Guilford-street frontage, whilst of the hinterland of eight acres nine-tenths may be covered with flats reaching a height of nearly 100 ft. It is useless regretting a misfortune of this kind without putting forward an alternative scheme for which an economic foundation can be found. Of those in the field the latest is that of Sir James Remnant, who for more than 25 years has been Member of Parliament for Holborn, one of the boroughs which stands to lose by obliteration of the Foundling site. He suggests the complete removal, to the place where Captain Coram's building now lies, of the Hospital for Sick Children, Great Ormond-street, which has been enlarged three times during the last generation and now contains 244 beds. It would be possible to sell the present site for a considerable sum, which could be devoted towards the new building, and by public subscription or otherwise some of the adjacent land could be kept as a playground for the children of the district. The price which would be asked for the nine acres is still uncertain, and the proposal will come up for reconsideration by the hospital board when further information is available. Meanwhile, it is understood, money has been promised in aid of the scheme, which has received the support of the council of the London Society and other bodies interested in maintaining open spaces. The work of the hospital is carried out in the face of serious obstacles in the present building in Great Ormond-street, the housing of patients, nurses, and residents all presenting difficulties. Thus the institution stands to gain by a change of situation, and it is believed that the board of management will wish to move to the Foundling site if the scheme is approved by King Edward's Hospital Fund for London. The Fund in its turn would be influenced in this direction if it were shown that reconstruction on the present site is impracticable. Whilst all will agree that much would be gained by transferring such important work to larger buildings in a more airy position, it must at the same time be considered whether the hospital ought really to remain in London at all. One institution at least for the treatment of acute diseases in children must remain to serve the city as a whole, but much can be said for moving all the others to the northern heights or other parts of the home counties, where the patients would enjoy an environment more healthy both from the physical and mental standpoint. The necessary consulting, distributing, and out-patient departments must remain in the centre of population, but a large proportion of cases would suffer no ill-effects by being transported in ambulances to the country. Many of the London hospitals have begun to act on this principle in a small way, and the Hospital for Sick Children has itself purchased a mansion and 75 acres of land at Tadworth in Surrey, forming a "recovery branch" with 42 beds. This was opened in June of last year. Should it be found undesirable or impossible to adopt Sir James Remnant's suggestion, and use the Foundling site for a new building, the institution might be well advised to transfer its centre of gravity to Tadworth. If no advantage is taken in this way of the Foundling site there will still remain a faint hope that it may be saved by an alternative scheme. Much support has been received for a proposal to use the building as part of a National Theatre, and if this were done by public subscription the surrounding district might become a university quarter and retain some at least of its open spaces.

CONDITIONS OF CHILDBIRTH IN INDIA.

THE difficulty of procuring accurate figures of maternal mortality in such a country as India, where neither registration of birth nor notification of death is compulsory, and where some cities attribute every death occurring within 40 days of delivery to childbirth, may be readily imagined. Dr. Margaret Balfour, lately chief medical officer of the Women's Medical Service in India, has recently carried out at the Haffkine Institute, Bombay, an investigation covering records of 11,343 cases of labour in maternity hospitals and wards in different parts of India, over a period of one year, in the hope of throwing light on the conditions of women in childbirth and on the principal causes of maternal death. Her findings were published in the *Indian Medical Gazette*, and have since been issued as a reprint. Broadly speaking, the maternal death-rate of India may be said to stand at from 10 to 15 per 1000, and in the material included in the inquiry, 31 per cent. of abnormal cases and 54 per cent. of deaths were found to be caused by diseases of pregnancy, as compared with 7 per cent. of abnormal cases and 35 per cent. of deaths among similar records taken from representative British hospitals. One of the most important causes of maternal death in India is the so-called anæmia of pregnancy, a condition almost unknown in Britain, but a terrible scourge in India and in some other tropical countries. Dr. Balfour herself followed a series of 150 cases in Bombay, and has published a separate paper dealing with this disease, which in Bombay City accounted for 61·9 per cent. of deaths reported. More than half the patients gave a history of sudden onset when previously in good health, usually between the fifth and seventh months of pregnancy. Symptoms included pyrexia, albuminuria, enlargement of the liver and spleen, œdema, vomiting, sore tongue, epistaxis, and diarrhœa. There was a high case-mortality, especially among the patients with diarrhœa; some of the non-fatal cases made a rapid recovery, while others were still in a seriously anæmic condition when they insisted on leaving hospital. In anæmia of pregnancy the fœtus does not suffer from the same blood condition as the mother, and when it dies appears to do so from lack of nourishment. Women leading confined, inactive lives, but receiving a good diet seem to be specially liable to the disease, as is evident from the high incidence among Mohammedan mothers. These women, however, show the same large proportion in regard to other diseases of pregnancy, due no doubt to the purdah system, which Dr. Balfour describes as "the custom probably most largely responsible for the disabilities of pregnancy in India." The Christian community is comparatively free from disease, for those who have had the advantage of education in mission schools have been trained in physical exercise and hygiene in a manner completely lacking from the life of the

Mohammedan and Hindu girl. Osteomalacia, or rather its consequences, figures as a serious cause of death in North India, but, curiously enough, was altogether absent from the returns of the Madras Presidency. Abnormal cases were much higher in proportion all round in the North, probably owing to the conservative views prevailing, women rarely going to a maternity hospital except for some abnormal condition. The degree of puerperal sepsis was impossible to define, as many deaths are not medically certified. The Indian woman appears to have acquired a good deal of immunity against sepsis, through generations of uncleanly practice by native midwives, doctors stating that they frequently perform such operations as version or application of forceps in conditions where anything approaching asepsis is impossible, and that the patients invariably recover without mishap. It seems much to be desired that systematic study and research into the diseases of pregnancy should be pursued in all schools of tropical medicine. Maternal deaths in India are largely due to diseases practically never seen in Britain, and, as Dr. Balfour points out, the remedy cannot be found simply by providing maternity wards or by training midwives.

MALARIA IN THE DUTCH EAST INDIES.

AN investigation of a malaria epidemic in the Dutch East Indies is reported by S. L. Brug and E. W. Walch, M.D., Dr.P.H., who have paid to England and America the delicate compliment of writing their report in English.[1] This report reveals an admirable piece of epidemiological research with some original observations on the habits of local mosquitoes. Having proved that an epidemic of some kind was in force from a rapid study of mortality statistics, the investigators incriminated malaria in acute form by finding that the parasitic index was definitely higher than the splenic index in the population. They proceeded to outline the epidemic area, first roughly from reports of the native magistrates and of local physicians, then more accurately by making blood and spleen examinations. This trail led them to the kampongs "situated immediately on the storm water canal and in the river Pepe." The former, it seems, is badly levelled, and in an unusually long dry season had been filled with stagnant pools. At the time of the investigation rains had flushed the canal and made it impossible to verify from collections of larvæ that this was indeed the source of the epidemic. But it has been noted down for future observation and sensible recommendations made. Of anopheles that are potential carriers examples were found of *rossi*, *aconitus*, *fuliginosus*, and *ludlowi*. But in the declining stage of the epidemic dissection of the anopheles was mostly negative. The writers draw attention to the fact that they caught *A. fuliginosus* "eagerly attacking people in the open at night-time."

THE PROPOSED BAYLISS-STARLING MEMORIAL

University College, London, will be for ever associated with the names of William Bayliss and Ernest Starling, who occupied chairs of physiology there during the fruitful years of a new scientific outlook. The opinion has been frequently and widely expressed that some fitting memorial should be made to record the great services rendered, both to the science of physiology and to its applications in the practical problems of medicine, by the labours of these two men. The patient zeal of the one, the fire and enthusiasm of the other, and the eagerness of both on all occasions to place their knowledge and experience at the disposal of other workers from any part of the world, have led to a universal appreciation of their services. The number of individuals in all countries who have profited directly from their help or indirectly by their influence is very great, and their writings stand as monuments to their industry and learning. A committee has now been formed to issue an appeal for funds wherewith to commemorate the connexion with physiology of these great partners in a manner of which they themselves would have approved; a material memorial or an annual lecture would have seemed a smaller thing to them than the provision of means whereby young workers of suitable training and ability might be attracted into their chosen subject. The personnel of this committee is as follows:—

Prof. J. Barcroft, F.R.S. (Cambridge), Mr. Samuel Bayliss, J.P. (Wolverhampton), Sir J. Rose Bradford, P.R.C.P., F.R.S., Prof. W. B. Cannon (Harvard), Prof. E. P. Cathcart, F.R.S. (Glasgow), Dr. H. H. Dale, Sec.R.S. (National Institute for Medical Research), Prof. J. C. Drummond (University College), Prof. C. Lovatt Evans, F.R.S. (University College), Dr. J. Fawcett (Guy's), Sir Gregory Foster (Provost, University College), Sir J. Kingston Fowler (London), Prof. A. V. Hill, F.R.S. (Foulerton Professor, Royal Society), Sir F. G. Hopkins, F.R.S. (Cambridge), Prof. J. B. Leathes, F.R.S. (Sheffield), Sir Thomas Lewis, F.R.S. (University College), Prof. Graham Lusk (Cornell), Sir Charles Martin, F.R.S. (Director, Lister Institute), Prof. M. S. Pembrey, F.R.S. (Guy's), Sir E. Sharpey-Schafer, F.R.S. (Edinburgh), Sir Charles Sherrington, F.R.S. (Oxford), Prof. G. Elliot Smith, F.R.S. (University College), Dr. Hubert Starling (Norwich), Prof. J. F. Stenning (Warden, Wadham College).

This committee is of opinion that the most fitting memorial would be the creation at University College of a Bayliss and Starling Studentship, open to any graduate in science of any university, or any graduate or undergraduate in medicine of suitable standing, to enable him to spend a year or more in such training in physiology and biochemistry as would fit him for research. A small part of the funds collected might be employed in the erection of a simple memorial tablet in the entrance hall of the Institute of Physiology. The governing body of University College has agreed to assist the appeal by remitting all fees payable by the selected candidate. Subscriptions may be sent to Prof. Lovatt Evans at the Institute of Physiology, University College, Gower-street, W.C. 1.

A BARONETCY has been conferred on Sir Richard Havelock Charles, G.C.V.O., K.C.S.I., who recently retired from the office of Serjeant-Surgeon to the King and was appointed honorary Serjeant-Surgeon.

THE following appointments have been made to His Majesty's Medical Household in Scotland: Prof. Ashley Watson Mackintosh to be honorary physician, Prof. John Marnoch and Prof. John Fraser to be honorary surgeons, and Mr. Arthur Havens Sinclair to be honorary surgeon oculist.

IN accordance with the will of the late Dr. Robert Thomas Nichols, the Royal Society of Medicine offers every three years a prize of £250 for the most valuable contribution by a British subject towards the Discovery of the Causes and Prevention of Death in Childbirth from Septicæmia. This year the prize has been equally divided between Dr. Peter L. McKinlay and Dr. Remington Hobbs.

AT the seventh International Congress of Dermatology and Syphilology, held in Rome in 1912, it was decided to hold the next congress at Copenhagen in 1915. Owing to the war this meeting was postponed indefinitely, but the Danish Dermatological Society now considers the time ripe for another international gathering, and it has decided to invite the congress to Copenhagen from August 5th to 8th, 1930. It is hoped that a large number of medical men from all countries will accept this invitation, and any suggestions for the success of the congress will be gratefully received by the Danish committee of organisation, whose secretary is Dr. S. Lomholt, Raadhusplads 45, Copenhagen.

[1] Report of an Investigation of a Malaria Epidemic in Solo, 1926, by S. L. Brug and E. W. Walch, Mededeelingen van den Dienst der Volksgezondheid in Ned.-hed. 1927. (Printed in Welterreden, Java.)

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXX.

THE TREATMENT OF OCCUPATIONAL (NON-MALIGNANT) DERMATITIS.

THOSE who are familiar with the increasing volume of literature on the subject of occupational dermatitis will realise that its treatment falls into three compartments—preventive treatment, immediate alleviation, and the treatment of sequelæ. The use of and responsibility for preventive treatment is in the hands primarily of the sufferer and to a lesser extent is divided between the Home Office, the local health authorities, and all employers of labour. The immediate treatment may be carried out by works' surgeries, by panel doctors, or by hospitals; and in the investigation and treatment of these cases every ancillary aid known to medical science may have to be invoked.

Prevention.

Some types of skin are more hazarded by occupation than others; patients whose bad circulation renders them susceptible to chilblains, the young, those who congenitally have an abnormally dry skin (xeroderma) and the rarer group of people who have hyperhidrosis of the palms, are all particularly liable to suffer from industrial dermatitis when exposed to deleterious dust or fluids. The rare type which exhibits on very slight irritation a vesicular interdigital eruption (cheiropompholyx) should above all others be excluded from occupational risks and retire to sheltered trades.

It is advantageous for employers to replace hand contact by machine labour whenever it is ascertained that bodily contact with industrial products is responsible for increasing the sickness-rate in an industry. Most notably was this done during the late war in factories where T.N.T. and poisonous gases were being made. Furthermore, a great deal of risk is eliminated by clean working; thus in such a simple occupation as machine-ruling for account books, dirty workers suffer from severe aniline dye dermatitis of the hands, whereas clean workers escape. Some, as their apprenticeship passes on, become cleanly, whilst others give up the trade. Instruction of the workers in the best method of setting about their jobs plays an essential part in the prevention of occupational dermatitis. Other protective measures include the introduction of exhaust fans and the arrangement of adequate washing facilities. Dermatitis is to be expected in bakehouses and factories where cold water is provided in the winter for washing, without soap and without towels. On the other hand, employees must be repeatedly informed that cleansing agents such as petrol, benzene, turpentine, and strong alkaline soaps are deleterious unless their use is exceptional; for dermatitis of the hands is quite often due not so much to occupation as to drastic cleansing. In some forms of work, where the hands are continually being immersed in water (fishmongers and barmaids) and in trades where there is a continual exposure to dry dust or alkalis (bakers or cement-workers), there is a constant loss of surface grease, the presence of which protects the skin and helps to keep it supple. Those exposed to such a risk often grease their skins freely every night with lanolin, lard, or similar substances, and so prevent or postpone the onset of dermatitis.

Immediate Treatment.

Treatment naturally depends on the nature of the cutaneous reaction. Should the patient show acute ulcers such as "pigeonneau"—i.e., the iris-like ulcer with central slough found in silica and arsenic workers—or the very acute ulcers found between the fingers of chrome-workers, or the large follicular pustules sometimes seen on the forearms of oil-workers, the immediate need is for frequent fomentations. Boric lint is to be avoided; plain white lint should be frequently reapplied during the day-time, and at night the limb should be powdered with pulv. zinc. oxid. et calomel. and dressed with dry gauze. In this way maceration and multiplication of the septic foci can be avoided.

More often the reaction shown consists of a red scaling eruption on the back of the forearms, extending as high as the elbow and complicated by small fissures in the webs of the fingers and on the knuckles. Here the most valuable application is the following liniment:—

℞	Calamine	35 grs.
	Solution of lime	½ oz.
	Olive oil	to 1 oz.

The best result is obtained if the patient is in bed between clean sheets with frequently changed body-linen; the cream is gently wiped on with cotton-wool three times a day and is allowed to dry without any external dressing. But if the patient returns to a home of dubious cleanliness, it is preferable to instruct him to clean the areas with a boiled bran bag and warm water twice daily, to apply the cream freely and cover the affected areas with a large dressing of white lint. The patient must be impressed with the necessity of avoiding scratching, which is liable to set up coccogenic dermatitis with the development of septic follicles or large bullæ and scabs, possibly followed by septic adenitis. It is not uncommon for the dermatitis to spread on to the forehead, face, and neck. In patients with a greasy skin, accustomed to the wearing of uncleanly thick flannel vests, dermatitis may involve the whole trunk in large red desquamating sheets with an approximation to exfoliative dermatitis at the height of the eruption.

The patient should always be removed from work at once and there should be no doubt about his certification. Responsibility for the condition of employees is apt to be disputed, and payment of sickness benefit withheld, so long as the practitioner does not clearly say whether the dermatitis is or is not occupational in origin, and it is in the patient's interest to make a plain statement on this point as soon as it is possible to do so.

In all but trivial cases the patient should be advised to go to bed. The bedrooms, as a rule, are the cleanest part of a working man's house, and in bed a man is naturally more anxious to recover than when he is wandering around his leisure haunts, an object of sympathy. It is only too common for such patients to be receiving ambulatory treatment for 18 months to two years before hospital aid is sought, and by that time the skin capillaries and nerve-endings have learned bad habits of permanent flushing and over-sensitiveness which may take much longer to undo.

Sequelæ.

The outstanding sequelæ of an attack of occupational dermatitis are dermatitis artefacta, stocking and glove erythemata, and chronic lichenisation. In young patients the return to work is often irksome and the lesson accidentally learned is utilised purposely to produce new lesions, which can only be cured by occlusive dressings. At the beginning of last year, for instance, I saw a girl with acid artefact ulcers, who in another employment at the end of the year appeared with a septic umbilicus from which I extracted two tin-tacks. In each case her motive was to leave a situation which she disliked, and she lacked courage to return home after the ordinary routine of giving notice.

The production of stocking erythemata is rather more subtle. Under this heading is comprised a group of patients who have received a definite injury of the skin which has become a site of local sepsis, and such patients present a red, scaling condition of their legs, which persists from 5 to 20 and sometimes 40 years from the date of their accident. These red legs rationalise the patient's mental conception of an anatomical leg. The eruption does not extend below the shoe level and ends in a fairly sharp line

just below the patella; that is to say, its distribution does not follow that of a vascular supply or a lymphatic tract, or the distribution of a nerve. It corresponds to that found in hysterical anæsthesia and contrasts sharply with what is seen in true neuritis. It will often be found, on close inquiry, that the original spread of the eruption was due to the employment of strong mercurial ointments. If such patients are admitted into hospital and their legs are dressed with the blandest applications and their hands are kept from all contact, the superficial inflammation will gradually subside, leaving pigmented, rather glistening dry skin of a normal pattern. In these cases great benefit is obviously obtained by the element of drama in treatment; the paint known as Sir Lenthal Cheatle's malachite green stings slightly when sprayed on the skin and leaves a vivid green colour, which is very satisfying to these self-centred people.

Among nervous patients after the general eruption has faded an irritating reddened area of skin may be left at the wrist or elbow; this by prolonged rubbing may become rough and thickened, standing out almost as a piece of shagreen leather in contrast with the normal skin. This patch of altered, but not pathological skin, is apt to be fiercely irritable at fixed times and causes great depression. In such circumstances one-third of a Sabouraud pastille dose of X rays, repeated in three weeks' time, is often magical in its effect. Continuance of irradiation is to be deprecated, although patients will press for it. Repeated exposure to X rays causes atrophy of the skin, recognisable by white scarring dappled with pigmented spots and red blotchy vessels. Such atrophic skin is fragile and vulnerable, and in later years is apt to undergo a malignant metaplasia. This sequence may be avoided by changing over to treatment by ultra-violet light, which should be administered in large doses, such as ten minutes of a Jesionek lamp exactly to the affected area at a distance of one foot; this exposure may safely be repeated after a fortnight's interval.

In all these cases no general medical counsels should be overlooked. Bad habits of constipation must be corrected and oral sepsis must be adequately treated. Malnutrition is often present owing to bad home cooking. A mixture of iron, strychnine, and arsenic should be prescribed for the pallid town-worker, while the nervous, quick, and fretful patient, more than others, should be aided by the early administration of bromides in adequate doses.

RHEUMATIC CONDITIONS IN SCHOOL-CHILDREN.

AN INVESTIGATION INTO GROWING PAINS AND NODULES (GRAINS).

BY MARY F. WILLIAMS, M.B. LOND., D.P.H.,
SENIOR ASSISTANT COUNTY MEDICAL OFFICER, WORCESTERSHIRE.

THE work here described is an endeavour to obtain definite statistical information in regard to "growing pains" and the conditions correlated with them. During the examination, in 1926 and 1927, of 1298 "routine" children over 8 years of age, in school, special attention was paid to the following points: (1) growing pains; (2) condition of teeth; (3) condition of tonsils; (4) cardiac conditions; (5) existence of nodules or grains.

Table I. gives the findings as regards growing pains:—

TABLE I.—*Semi-Urban Areas.*

Age group	8–10.	10–12.	12 upward.
Number with growing pains..	96	35	43
Number of children examined	216	88	203
Percentage with growing pains	44·4	39·8	21·2
Rural Areas.			
Number with growing pains..	160	58	87
Number of children examined	324	135	311
Percentage with growing pains	49·4	43	28·0

It would appear that "growing pains" are at their maximum from 8–10 years (unless the correct age is below this), and that there are more cases in rural than in semi-urban areas. The latter point is confirmatory of figures obtained in 1912,[1] when special attention was paid to the frequent existence of pyrexia and the heredity figure of 0·46 was obtained for "rheumatism."

Criticism is sometimes directed against the varying numbers found by different examiners to be suffering from growing pains. This condition is so lightly regarded by both parents and children that no mention of it is, as a rule, made, unless the direct question is put. Since writing these notes, I have examined 200 children in the usual way, except that in no case have I put either of the two usual questions: "Do you ever ache anywhere"; or "Do you have growing pains?" In these 200 children neither parent nor child has once mentioned growing pains, though in some cases I knew from other sources of information that they existed. To obtain accurate information the question must be put systematically to every child old enough to answer intelligently, or at least to every parent.

It is sometimes said that children answer haphazard when asked as to "growing pains," but this has not been my experience. In many cases a previous record of them existed, unknown to the child, and the answers were almost always in accord. For instance, in one school, 11 children were investigated in 1925, and again in 1926 or 1927. The children, 7 in number, who stated they had growing pains in 1925, gave the same answers, 3 in 1926, and 4 in 1927. Four children, in 1925, stated that they had not had growing pains, and of these 3 gave the same answers in 1926, and 1 stated he had had them quite recently. It is difficult to believe 11 children would remember for either one or two years the answer they had given to a question so long ago. If the growing pains were fact the answers are explained.

At the end of 1926, after the examination of 650 children, it became clear that the carious teeth were not correlated with growing pains. There were only 19 cases in which there were many carious teeth, and of these 12 were among the non-rheumatic. The teeth were good as a whole, and greatly superior to 10 years ago.

Table II. gives the percentage findings for tonsils:—

TABLE II.

—	Tonsils not visible.	Moderately enlarged.	Much enlarged.
With growing pains ..	60·2	29·1	12·6
Without growing pains..	66·7	23·6	9·7

Bearing in mind the liability of rheumatic children to tonsillitis, it becomes evident that some of them must have been seen at some stage of an attack (and, in fact, some of them are so marked), and that these would be included in those noted with "enlarged tonsils." Hence it does not appear that there is any significant difference between the rheumatic and the non-rheumatic in regard to the more chronic enlargement of tonsils.

[1] A Statistical Study of Oral Temperatures in School-children. By M. Williams, M.B., B.S., D.P.H., Julia Bell, M.A., and Karl Pearson, F.R.S.

The cardiac conditions were noted under the following headings: apex in or outside nipple line; large visible area of pulsation; bruit; thudding first sound; accentuated second sound; thrill.

Table III. gives the findings as to the existence of slight cardiac defects in children who had, or had had, growing pains, at the various ages:—

TABLE III.

Age	8–10.	10–12.	12.	13–14.
Percentage with cardiac defect	25·2	40·9	70·4	62·6

It would appear that the effect on the heart is most common at 12 years, and then begins to pass off.

It has long been known that in cases of serious rheumatic disease subcutaneous nodules are sometimes felt. An addition to our knowledge has recently been made by Dr. Vincent Coates and Dr. R. E. Thomas.[2] On a visit to Bath by the writer, Dr. Coates very kindly demonstrated tiny nodules and showed how to find them.

In the present series an attempt has been made to assess the value of these "nodules." They are to be found most easily over the ulna or over the spine. The nodules under consideration are so small that the word granule better describes them, or perhaps grain would be even more descriptive. On passing the tip of the fingers horizontally across the spine, there is a sensation as if one or more millet seeds were embedded in the subcutaneous tissue and slipped under the finger. In examining the ulnar region, the right hand must be used for the right arm and the left for the left arm. The grains are not as a rule tender. In the first 484 children examined, time only permitted the examination of the arm region. In the next 266 children both arms and spine were investigated, and this series convinced the writer that much less time and trouble is required to find the grains over the spine than those over the ulna. In the first series of 484 children Table IV. records the result:—

TABLE IV.

		Grains over ulnar.	Per-centage.
Children with growing pains ..	197	131	66·5
Children without growing pains ..	287	29	10·1

(Dr. Coates's percentage for children regarded as rheumatic was 79·5.)

The second series in which arm and spine were examined, gave results as shown in Table V.:—

TABLE V.

—	—	Grains over ulna.	Grains over spine.	Grains over both.
Children with growing pains ..	123	75 (61·0 %)	81 (66·0 %)	62 (50·4 %)
Children without growing pains ..	143	13 (9·1 %)	15 (10·5 %)	5 (3·5 %)

In the remaining 199 children the spinal area only was examined (Table VI.).

TABLE VI.

		Grains over spine.	Per-centage.
Children with growing pains ..	166	133	80·1
Children without growing pains ..	263	19	7·2

The three series of examinations all tend to show that these grains are a frequent concomitant of early rheumatism. The question that needs elucidation is whether they occur in other conditions, or whether the children who had no other sign of rheumatism at the moment are in reality already infected. In support of this view it may be mentioned that some of these cases were in children of rheumatic heredity.

Finally, I should like to draw attention to the frequency of epistaxis in rheumatic children. Definite figures cannot be given, but the frequency appears to be more than mere chance. The frequency of mild rheumatism in children suggests that a slow process of immunisation of the race is begun.

[2] Rheumatic Infection in Childhood, by Dr. Vincent Coates, Brit. Med. Jour., March 26th, 1925; and Rheumatic Infection in Childhood, by Dr. V. Coates and Dr. R. E. Thomas, THE LANCET, 1925, ii., 326.

TUBERCULOSIS CONFERENCE.

OXFORD, MARCH 29TH–31ST.

A PROVINCIAL joint meeting of the Tuberculosis Society and the Society of Superintendents of Tuberculosis Institutions was held at the Dunn Laboratory, Oxford, from March 29th to 31st.

LUPUS AND ITS TREATMENT.

At the first session, Sir FARQUHAR BUZZARD presiding, a discussion on lupus and its treatment was opened by Sir STCLAIR THOMSON (President of the Tuberculosis Society). He reminded the meeting of certain well-known features of lupus. It is a chronic tuberculous condition, liable to undergo alternate periods of activity and arrest, caused either by bovine or human bacilli, and occurring as a local manifestation, it is more common in females than in males in the proportion of 3 to 1, and commences particularly between the ages of 5 and 14. It is relatively rare in America and Canada, and in Europe is commoner in the northern parts, in cold weather than in warm, and in the poor rather than in the well-to-do.

In the upper respiratory tract lupus affects chiefly the nose, the pharynx, and the epiglottis, occasionally the larynx, and rarely the tongue or buccal mucous membrane. Lupus in the nose is often associated with lupus on the cheek, but whether the nasal lesion is always primary is a debatable point. He suggested that the nasal lesion often escapes recognition, perhaps because it may be hidden beneath the blades of the nasal speculum. He said that if adrenalin and cocaine were placed on a suspected place, the healthy mucous membrane blanches, but the lupoid area remains congested. Pharyngeal lupus is not always secondary to nasal. Lupus in the epiglottis and larynx differs markedly from tuberculosis in these situations in respect of virulence, for advanced lupoid ulceration of the epiglottis may be almost symptomless, and the same is true to a less extent of lupus in the pharynx. He described three cases to illustrate these points.

He asked if any of the audience could answer certain questions, why is lupus more common in females, why is it rare in America, why is it most common in the nose, why may pulmonary tuberculosis lead to laryngeal lupus but not to nasal? As regards treatment he relied on sanatorium principles and the proper use of the galvano-cautery. Finally, he showed several very interesting drawings of the different forms of lupus and of the results of treatment.

Dr. W. J. O'DONOVAN (London Hospital) showed a number of interesting slides illustrating a very early nodule, lupus in a mother and child, Dr. Sequeira's first natural sunlight treatment with a lens and the modern light department at the hospital, numerous cases, some of historic interest, of the results of treatment of facial lupus, lupus in operation scars, certain cases of differential diagnosis, pigmentation, and acid burns. In summarising some of the results of his experience, he emphasised the importance of general treatment which greatly enhances the value of local applications. Local treatment, he said, if drastic enough, will always get rid of lupoid patches, but some agents produce intense scarring. In his experience X ray treatment, if sufficiently thorough to cure the lupus, is always followed by carcinoma. He had found that in some cases light treatment had been unsuccessful until salvarsan had been given, even though a most careful inquiry had failed to discover

a syphilitic element. Very occasionally lupus heals spontaneously. He emphasised the necessity of coöperation with other departments, particularly those of the ophthalmologist, laryngologist, and surgeon. He concluded with a warning to search for other lupoid patches in addition to those for which the patient seeks treatment.

Discussion.

In the discussion, Dr. COFFIN agreed that in his wide experience in America lupus was very rare, and that cases of facial lupus such as Dr. O'Donovan had shown were almost unknown.—Dr. E. WARD (Devon) testified to the results obtained at the London Hospital. He asked whether Dr. O'Donovan would define lupus and explain the difference from conditions called, for instance, scrofuloderma.—Dr. E. MALLAM (Oxford) said that he had obtained good results in lupus erythematosus from the use of chrysolgan, and suggested that large doses of potassium iodide might be tried. In this connexion Dr. S. V. PEARSON (Mundesley) asked whether the claims of successful treatment of lupus erythematosus with triphal could be substantiated.—Dr. J. WATT (Godalming) said that in his sanatorium cases of tuberculosis in the mouth were very rare.—Dr. A. NIVEN ROBERTSON (Chesterfield) asked what was the origin of lupus, and whether light treatment could be used for lupus of the upper respiratory tract.

Sir STCLAIR THOMSON, in reply to the last question, said that he had failed to get good results, and that he had had no success with potassium iodide. He emphasised again the clinical differences between lupus and tuberculosis as they affect the nose, pharynx, and larynx, and gave an extremely clever imitation of the voices of four patients with cancer, syphilis, lupus, and tuberculosis, respectively, of the larynx.

Dr. O'DONOVAN said that he had not found that patients could tolerate the large doses of iodide suggested, that the pathology of lupus erythematosus was doubtful, and that there was no explanation of the reason why tuberculosis cutis should sometimes be indolent, sometimes ulcerative, sometimes liable to dissemination. The different names were due to these clinical variations.

THE POTENTIALLY TUBERCULOUS CHILD.

At the second session Sir STCLAIR THOMSON took the chair for a discussion on the potentially tuberculous child considered from the administrative point of view.

Dr. A. L. ORMEROD (M.O.H. for Oxford) said that there was no one health service responsible for the care and treatment of the potentially tuberculous child, and that in practice those who had to face the problem were forced to use or adapt such facilities as were at their disposal to meet the individual needs of different cases. Cases cannot remain on the dispensary register indefinitely as "doubtfully tuberculous," so it had been arranged in Oxford, where the medical officer of health and his assistant are clinical tuberculosis officers and school medical officers, that one weekly session should be devoted to these cases and that only the other two sessions should rank for the tuberculosis grant. At this clinic careful observation of the children is carried out, the reference of cases and their regular attendance is assured by its close connexion with the school medical service and the education authority, and the domestic environment is supervised by the medical officer of health's nurses. Any delicate child can attend the clinic. Outside assistance to the child or the family, such as the provision of extra nourishment or of clothes, can be obtained from certain public or charitable organisations. As unsatisfactory home conditions are often the main cause of the children's ill-health, and as the housing problem is no less difficult in Oxford than elsewhere, some form of residential treatment is necessary. Something has been done in this direction by boarding out children in a small house about 20 miles from the city. Only three can be accommodated at a time, so that since 1920 the total amounts only to 155, but the results have been very gratifying. In some instances the good work was undone when the child returned home, but that was inevitable. "The worst possible home condition," said Dr. Ormerod, "is an ignorant and careless mother." The evolution of this scheme, which would appear to be the best solution of the problem, makes it clear that the various public health services in a city like Oxford are inter-dependent, and the work of the medical officer of health who controls them would be much easier if a block grant were made and more freedom were allowed for its apportionment to meet varying local needs.

Dr. G. MACDONALD (Battersea) said that he was medical officer to a day school (Springwell House Open-Air School, Clapham Common), to which were admitted only notified cases of tuberculosis. They were potentially tuberculous only in the sense that many who had relatively slight degrees of glandular or surgical tuberculosis were possible cases of frank pulmonary tuberculosis later on. After tracing the history of open-air schools, and defining the four varieties, he described the routine of Springwell House. It is really a day sanatorium, accommodating 125 children, who are taught in the open air all the year round, except on some half-dozen occasions when indoor classrooms have to be used. Heliotherapy is not practised. Very special attention is given to the feeding, and periods of rest are insisted on before and after the mid-day meal and after tea. There is close coöperation with the dispensary service. In addition to the ordinary elementary education, there are vocational classes in gardening, millinery and lingerie, and a commercial class. After-care is particularly necessary for children who have attended special schools. A "school-leaving conference" is held after each term at Springwell House, and attempts are made to find suitable employment. Records of the subsequent careers of the children are kept. At the end of 1926 there was accommodation in the open-air schools of England and Wales for 5000 debilitated children, and for 500 in schools of the type of Springwell House. In London, excluding open-air classes, only one child attends an open-air school for every 500 at the elementary schools. The proportion is far too small, but it must be remembered that education in the open-air school costs three times as much, and that the selection of an open yet accessible site is difficult. The results are very satisfactory, the improvement in general health, the gain in weight, and the freedom from infectious illnesses being particularly striking.

Dr. ESTHER CARLING (Peppard) dealt with the residential open-air school. Such schools, as Sir George Newman said in his annual report for 1920, "may be provided as part of a tuberculosis scheme and utilised for children suffering from incipient tuberculosis or those in whom (owing to the presence of anæmia, malnutrition, &c.) the existence of tuberculosis is suspected. Such institutions undoubtedly serve a useful purpose in preventing the onset of definite tuberculosis." Unfortunately the attitude of the Ministry towards the potentially tuberculous child seems to have changed. Suspects cannot stay at the school for more than a few weeks unless a definite diagnosis of tuberculosis is made. Notification as tuberculous is therefore a means of ensuring prolonged treatment, but is undesirable in practice if there are still reasonable doubts about the diagnosis. Dr. Carling therefore proposed the following resolution: "This meeting desires to establish the claim of the potentially tuberculous child in rural areas to recognition as a suitable case for treatment in a county sanatorium school *without notification*." Looking back over 20 years, Dr. Carling was struck by the contrast between the procession of "lack-lustre" entrants and that of the "well-groomed" children leaving some nine months later. These children certainly needed treatment; they responded to it, but were they really tuberculous? The ideal course is to extend the

period of observation allowed so as to cover the full period of requisite treatment, but the insurmountable barrier appears to be that the treatment of tuberculosis is paid for by the Ministry of Health, and the prevention of tuberculosis in children of school age is a charge upon the school medical service. Notification of delicate children as tuberculous has several disadvantages—unreliable statistics are produced; unnecessary expense is incurred; unsuitable orientation is engendered (the hospital as against the educational outlook); the label of tuberculosis is a handicap in seeking employment later; there is possible infection from open cases; and, perhaps, there is the loss of treatment of the actual debilitating condition through misplaced measures.

Discussion.

In the ensuing general discussion, Dr. WARD said that the tuberculosis scheme was meant to deal with the definitely tuberculous patients, and the education authority with the delicate child. He drew attention to the importance of the coöperation of the general practitioner in any scheme.

Dr. W. A. DICKSON (Gloster) agreed that open-air schools were impossible in rural areas, and that residential institutions must take their place. He favoured notification in cases needing treatment, and thought that its disadvantages to the child were exaggerated.

Dr. A. NEVILLE COX (Brighton) thought that most tuberculosis officers were too busy to take charge of a comprehensive scheme for dealing with the delicate children. He asked whether such children did, in fact, become frankly tuberculous in later life.

Dr. W. STOBIE (Oxford) disliked the term "potentially tuberculous." The delicate child fell into one of four groups, the ill-nourished, the adenoid, the parasitic, and the subject of acidosis.

Dr. G. T. HEBERT (St. Thomas's) admitted that the term referred to was unsatisfactory. He would add another group to Dr. Stobie's, the child suffering from varying degrees of chronic interstitial fibrosis and pulmonary catarrh.

Dr. F. R. WALTERS (Crooksbury) said that contact did not make a child potentially tuberculous.

Dr. L. T. BURRA (Bucks) thought that the question of treatment depended largely on the question of what were the criteria for the diagnosis of tuberculosis in the child, and regretted that this subject should not have been discussed.

It was decided to defer Dr. Carling's motion until notification and the clinical diagnosis had been considered by the Society.

THE TREATMENT OF HÆMOPTYSIS.

At the third session Dr. PEARSON took the chair at a discussion on the Treatment of Hæmoptysis in Pulmonary Tuberculosis. Dr. CLIVE RIVIERE (London) said that a system of treatment depends upon a knowledge of the underlying pathological factors. Hæmpotysis is due to the rupture of vessels; diapedesis can account only for small continuous bleedings. The rupture of the vessel is due either to a local spread of disease or to congestive processes. There remain, however, several unexplained anomalies, the rarity of hæmoptysis in children, and its complete absence throughout the course of some fatal cases; and much work is still to be done on the influence of secondary organisms, particularly spirochætes. He approached the subject of treatment by following the scheme laid down by the author of a recent small text-book, and pointed out where he agreed and disagreed. The author had said there were two main objects: (1) encouragement of immediate arrest of the bleeding, and (2) prevention of its recurrence. The first was to be attained by correct posture, by avoidance of effort, by application of the ice-bag, and by removal of blood from active circulation. Dr. Riviere agreed with these measures as well as with the withholding of morphia, and hoped to hear the views of the meeting about the latter point. He agreed that spontaneous arrest often occurs. "How often," he said, "must Mother Nature have put her tongue in her cheek as she turned off the tap just as we had applied our most futile remedies." For the prevention of recurrence neither Dr. Riviere not his author places much reliance on the use of drugs. Retardation of the pulmonary blood-flow is more important than decrease of the pulmonary blood pressure, and neither vaso-constrictors nor vaso-dilators appear to have the desired effect. In fact, the flow is best controlled by physical measures. Dr. Riviere then dealt with coagulants, which can be supplied either from within or from without. Autotransfusion is a natural process after hæmoptysis, and is assisted by salt action. Coagulants from without include blood serum and the transfusion of whole blood, calcium, gelatin, coagulen-ciba, hæmoplastin, thromboplastin, and fibrinogen. Summarising, Dr. Riviere said that there were three objectives: (1) to close the bleeding vessel (by reflex action, or collapse of lung); (2) to reduce the pulmonary blood-flow (by damping down the systemic circulation); and (3) to increase the coagulating power of the blood (by salt, intramuscular calcium chloride, transfusion, &c.).

Dr. PEARSON said that in his experience as a sanatorium superintendent hæmoptysis was neither a common nor a serious occurrence. He believed that the régime tended to prevent it.

Dr. HEBERT, while recognising the great value of morphia in obstinate cases if skilfully used, thought that junior house officers should be discouraged from using it. He thought that the key to treatment lay in diagnosis of the actual cause of the bleeding. A large initial hæmoptysis was from a vein and did not need medicinal treatment; a large hæmoptysis in a chronic case often came from an artery in a cavity and called for drastic treatment; small hæmoptyses in chronic cases might be congestive (venous bleeding) and therefore need no treatment, and in active cases (arterial bleeding) the treatment varied according to circumstances.

Dr. COX advised placing the patient on the side from which the blood was coming. He drew attention to epidemics of hæmoptysis.

Dr. ROBERTSON said that he had correlated hæmoptysis with varying meteorological conditions. He drew attention to the fact that tuberculous broncho-pneumonia followed hæmoptysis in some cases, but not in others, and suggested that deficient or effective broncho-constriction was the deciding factor.

Sir STCLAIR THOMSON said that the use of morphia ought to be prohibited after laryngo-fissure. Cases of aspiration pneumonia after that operation were almost always due to its use. In cases of tuberculous laryngitis his watchword was "masterly inactivity." From what he had heard, the same appeared to apply to hæmoptysis.

Dr. W. C. FOWLER (Pinewood) asked whether any conclusions could be drawn from the occurrence of pyrexia before the hæmoptysis, or from a low grade of pyrexia after it in a previously afebrile case.

Dr. BURRA said that a very careful investigation which he had carried out had failed to reveal or suggest any connexion with meteorological conditions and the incidence of hæmoptysis.

Dr. MACDONALD asked whether hæmoptysis in the tuberculous always indicates an active process.

Dr. RIVIERE, in reply, said that he believed that hæmoptysis could occur in the absence of appreciably active tuberculosis, and that in such cases a low grade of pyrexia after the recurrence was due to the absorption of serum.

INTESTINAL TUBERCULOSIS.

At the fourth session Dr. WALTERS presided over a discussion on Intestinal Tuberculosis.

Prof. N. J. STEWART (Leeds) said that infection of the intestinal wall occurred from the lumen, from lymphatics, or from the blood stream. He did not propose to deal with the latter, which was merely part of a generalised infection, nor with cases of tabes mesenterica in which the minute path of entry in the intestinal wall had healed. Infection

from the lumen is caused by bacilli ingested with the food, but especially by bacilli contained in swallowed sputum. Thus he had found definite tuberculous enteritis in 50 per cent. of patients dying of pulmonary tuberculosis. In 85 per cent. of 500 cases investigated the lesion was in the ileo-cæcal region, it was ulcerative, obtrusively tuberculous, and rarely perforative. Adhesions were frequent, and intercommunications not uncommon. Complete healing of ulcers was rare. Infection by means of lymphatics may be responsible for the so-called hyperplastic type, which also is commonest in the ileo-cæcal region. In 18 years he had examined carefully 21 specimens of this condition, and he showed some very beautiful slides of one of these, illustrating the dilatation of the ileum, the muscular hypertrophy of its wall, the freedom from typically tuberculous ulceration (though small non-tuberculous superficial ulcers are present), and the mass of atypical tuberculous material in which tuberculous glands are often embedded. In this particular specimen a polyp apparently acted as a ball-valve to an already almost completely stenosed ileo-cæcal opening. Considering the diagnosis of the hyperplastic type, he showed a slide giving the age incidence of cancer in this situation. In 84 per cent. of cancer cases the age was over 40, and in 80 per cent. of hyperplastic tubercle was under 40. He asked for information about the radiological appearances of the condition. In conclusion, he suggested that in patients with secondary enteritis massive infection played the chief part, whereas with the hyperplastic type there was considerable local resistance.

Mr. L. E. BARRINGTON-WARD (London) said that intestinal tuberculosis could be regarded from two aspects, that of the sanatorium officer, who had to deal with it as a complication of pulmonary tuberculosis, and that of the surgeon who in his work at a general or children's hospital meets it unrelated to a lung infection. Dealing briefly with secondary enteritis, he noticed that Brown and Sampson believe it to be curable if recognised and treated in time. He considered the symptoms and diagnosis. Removal of the affected bowel is rarely feasible, but ultra-violet rays would appear to have a beneficial action. In the other type, referred to by the previous speaker, a palpable tumour is associated with the clinical features of a chronic small intestine obstruction. Exact diagnosis is usually impossible, and often is difficult even on incision of the mass removed. Resection is a satisfactory method of treatment; if that is impracticable, relief may be given by short-circuiting. Obstruction from cicatrisation of ulcers, intussusception excited by a tuberculous ulcer of the ileum, and the rare cases of perforation also concern the surgeon.

Dr. MARCUS PATERSON (Colindale) said that in adults primary tuberculous ulceration of the intestine is almost unknown. Ulceration secondary to pulmonary tuberculosis is only too common, and therapeutic measures are directed chiefly towards alleviating symptoms. In his experience, the outstanding of these had been offensive diarrhœa, associated with extreme debility and perhaps with bed-sores. In these cases an incorrect diet—namely, milk and slops—has been the cause. As soon as he put the patients on as solid a diet as possible and restricted the milk supply to a minimum, the diarrhœa almost ceased and the general nutrition improved. The widespread teaching that milk was the staple food for a patient with diarrhœa was quite fallacious. At Colindale Hospital an investigation showed that in 133 autopsies tuberculous enteritis was found in over 50, but when on a suitable diet only 3 per cent. had had diarrhœa.

Discussion.

Dr. WALTERS asked for an opinion on two points, whether the dyspepsia of early tubercle might not be caused by unrecognised intestinal disease, and what medicinal remedies were of most value in practice.

Dr. RIVIERE said that probably in certain cases tuberculous ulcers in the intestine did retrogress and heal. Being accompanied by few symptoms, their presence was difficult to diagnose. He mentioned that he had seen two cases of tuberculous ulceration in the stomach from rupture of a caseous bifurcation gland into the œsophagus. He was much interested in Prof. Stewart's suggestion of a retrograde infection of the intestine from mesenteric glands, and pointed out its analogy to retrograde involvement of the lung.

Dr. PEARSON pointed out that Dr. Walther was one of the first to draw attention to the ill-effects of milk. He regretted that no radiologist was present who could make an authoritative statement on diagnosis by the X rays.

Dr. WARD agreed that intestinal tuberculosis was commoner than was generally supposed in England, and he said that milk could be given to some cases without causing diarrhœa. He had grounds for supporting the previous speaker's suggestion that tuberculous enteritis might be associated with hyperchlorhydria.

Dr. TURNER asked whether in certain cases of appendicitis accompanied by tabes mesenterica the former might not be an atypical tuberculous condition.

Dr. H. G. TRAYER (Timperley) agreed that recognised cases of tuberculous enteritis were much less common than in America. In a series of cases of enteritis which he had investigated he found involvement of the cæcum in very few. He suggested rice water and condensed milk as a diet suitable for some cases.

In reply, Mr. BARRINGTON-WARD said that milk was quite unsuitable for patients after an intestinal operation, and Dr. PATERSON said that condensed milk might well be a suitable food for patients with tuberculous enteritis, because it did not contain the host of organisms present in raw milk.

CERTIFIED MILK.

THE production and distribution of milk are matters of the foremost importance to the nation, and certainly the medical profession does not need this information; yet it is open to question whether doctors realise what is being done throughout the country to improve our food-supply in these respects. The grades of milk licensed by the Ministry of Health are several, and as the names attached to these grades are not immediately self-explanatory, the large reforms which have taken place escape attention. The remembrance of a bad old state of affairs obscures the present and far better conditions. The risks of milk in the raw state, as an unrivalled medium for the spread of dangerous contamination, make it necessary that in outbreaks of an infectious character the medical man should inquire into the milk-supply, but the fact should not obscure the knowledge that clean milk is now being produced and placed on the market with a supervision and confidence which is largely similar to that given to water-supply in large towns. It must be admitted that it is not yet possible to ensure the supply of pure raw milk to the whole population of our large cities, so that resort is had to pasteurisation for security in dealing with large quantities from many different sources, but medical men should be aware, perhaps more generally than they are, that a diet of fresh raw milk, Certified or Grade A (tuberculin tested) milk will carry with it none of the familiar risks.

The two highest grades of milk are Certified and Grade A (tuberculin tested) which are produced at farms licensed after due inspection by the Ministry of Health from cattle that have been proved to be free from tuberculosis by the double tuberculin test performed every six months by a veterinary surgeon, either intradermally and ophthalmic, or subcutaneous and ophthalmic. The difference between these two grades of milk is that Certified is bottled on the farm directly after milking, whilst the T.T. milk is run into sterilised churns and sent to the retailer who is licensed by the local health authority to bottle it

apart from ordinary milk; or it may be sent in the sealed churns to any large institution such as a hospital or school. In Certified milk no *coli* bacilli are allowed in 1/10th c.cm. and not more than 30,000 bacteria in 1 c.cm. of milk, whilst in T.T. milk no *coli* are allowed in 1/100th c.cm., and not more than 200,000 bacteria in 1 c.cm. The lower standard of bacterial content is also allowed in the third grade of milk, the ordinary Grade A. In this grade the cattle are open to a quarterly inspection by a veterinary surgeon but are not subjected to the tuberculin test.

The production of these grades of milk is now watched over at every stage to ensure cleanliness and sterility; the cleaning and grooming of the cow receives attention as well as the sealing of the bottle that goes to the consumer. The scrubbing of the hands of operatives and the sterilisation of utensils follow the procedure of the operating theatre in large part, while milking machines are coming more and more into use—a year's experimental research with two of these machines at the National Institute for Research in Dairying at Shinfield has proved that they are capable of producing without fail month after month an exceedingly low bacterial count as long as they are properly looked afrer. With mechanical milking machines which can always be brought into a condition of proved cleanliness and with milk bottled at once with every sterile precaution, the risk of the carriage of infection should be so minimised as to be abolished, and the attitude that milk must be avoided unless sterilised or pasteurised becomes unreasoning, though the question of pasteurisation remains unanswered. Pasteurised milk, if given as a diet, must be supplemented, but to what extent this is necessary has received no final proof. There is need of disinterested experiment to arrive at the results of a fresh clean raw milk as against those of pasteurised milk—the differences observed in the health, growth, and development of the growing child should be observed far more closely than is at present the case.

At the World's Dairy Congress, to be held in the United Kingdom this summer, an opportunity should be offered for the public and the medical profession alike to became intimately acquainted with every aspect of milk production from the cow to the consumer, and it is to be hoped that at this Congress the question of testing cattle for tuberculosis will be carefully considered. In the meantime by prescribing Certified or Grade A (tuberculin tested) milk, medical men will be doing the best for their patients, while incidentally those British farmers who have gone to the length of freeing their herds of tuberculosis will be encouraged.

Public Health Services.

The Responsibility of the Part-time M.O.H. for the Diagnosis and Removal of Infectious Cases.

A week or two ago we commented upon a dispute between a rural sanitary authority and its medical officer in regard to a case of scarlet fever removed to hospital on a fellow-practitioner's notification. On the one hand, some doubt was expressed at a meeting of the Council as to the correctness of the diagnosis and as to the obligation of the medical officer of health to confirm it before the patient's removal to hospital. On the other hand, the medical officer contended that it was for the attending practitioner to make the diagnosis; in a mild attack of scarlet fever the rash might be fleeting, and it was impossible in a large rural area for the M.O.H. to see every such case the same day; moreover, he could not visit unasked, except with an entrance order. We now understand from the M.O.H. concerned that his action was fortified by two letters received from the Ministry of Health, of which the relevant portions read as follow:—

1. I am directed by the Minister of Health to state that it is not the duty of a medical officer of health in ordinary circumstances to examine patients who have been notified to him as suffering from infectious disease, though it is generally desirable in the case of small-pox or other unusual form of infection. He is required, however, to satisfy himself either directly or through a member of his staff that all proper precautions are taken to prevent the spread of the disease. Where, for the purpose of carrying out his duties under the Public Health (Pneumonia, Malaria, Dysentery, &c.) Regulations, 1919, or of advising as to measures to be taken for preventing the spread of infection or of confirming the diagnosis in special cases, a medical officer of health deems it necessary to examine a patient, the Minister considers that any such examination should, wherever practicable, be made in consultation with the patient's medical attendant.

2. I am directed by the Minister of Health to state that he considers that the responsibility for deciding whether in the interests of public health a patient should be removed to the isolation hospital rests entirely with the medical officer of health. For this purpose it is not necessary that he should visit all cases personally. The usual practice is for a visit by the sanitary inspector, who records all the particulars and forthwith reports to the medical officer of health. On this report the decision to remove or not remove the patient rests. It is, of course, desirable that the medical officer of health should be guided by the opinion of the medical practitioner in attendance as to whether the condition of the patient admits of removal.

These letters set out the position clearly enough and completely justify the action of the M.O.H. It may be added that in the particular case the diagnosis of scarlet fever was confirmed by the subsequent course.

Reports of Medical Officers of Health.

Ilford.

We have received from Dr. A. H. G. Burton the first of the health reports for the year 1927.

The Registrar-General's estimate of the population of the borough was 108,310. The birth-rate for 1927 was 15·8; the death-rate, 9·6; tuberculosis-rate, 0·65; the cancer-rate, 1·28; the death-rate from respiratory diseases and influenza was 1·6, and the rate from organic disease of the heart, 1·6. Of the death-rates calculated per 1000 births the neonatal was 19·3, the infant mortality 44, the rate from diarrhœa and enteritis under two years 4·8, and the maternal rate from childbirth 3·0.

Dr. Burton thinks that the actual population is between 120,000 and 130,000, and in support mentions that there were 61,000 persons on the voters' list in the autumn of 1927. The rapid growth of Ilford is also shown by the fact that there are 14,206 children on the school rolls, as compared with 10,981 in 1922. Owing to the prevalence of both scarlet fever and diphtheria the accommodation of the isolation hospital was strained to its utmost. Only one nurse contracted diphtheria and she had not been immunised. Immunisation has been adopted against both diphtheria and scarlet fever for the staff. The question of offering immunisation to parents for their children is under the consideration of the health committee, and Dr. Burton instances Holborn, Camberwell, Deptford, Westminster, Battersea, and Tottenham in the London district as having adopted this practice. The cubicle wards in course of completion at the hospital will increase its efficiency, but further extensions will be needed before long.

The meat regulations are being complied with by the Ilford butchers in an exemplary manner. The milk-supply is also receiving careful attention. In September a sample of tuberculous milk was obtained from a Romford retailer, who was vending milk in Ilford. The Essex county veterinary inspector reported one cow with lumps in the udder, but as the microscopical examination did not reveal tubercle no further action was taken. It was pointed out to the clerk of the Essex County Council that microscopical examination alone was unsatisfactory, and that a biological test was needed. A further Ilford sample from this cow was found to be tuberculous, but the Essex County Council had a sample examined biologically with a negative result. In reply it was

pointed out that three laboratories confirmed the fact that this herd was supplying tuberculous milk. Ultimately in December this cow was submitted to a tuberculin test, gave a positive result, and was slaughtered. It was found to be suffering from advanced tuberculosis, with lesions of both lungs, mediastinal glands, and mammary glands. Subsequently a further sample of milk from the retailer was found to be free from tuberculosis. The particulars of this case were reported to the Ministry.

An open-air school with accommodation for 100 children is nearing completion, and is to have equipment for artificial sunlight treatment. This treatment is already in operation at the isolation hospital for cases of surgical tuberculosis, and Dr. Burton reports that, although the results are good, they do not compare with the benefit obtained from natural sunlight in the summer months. The problem of the mentally defective children still remains to be dealt with in Ilford and also that of the child with minor physical defects, who requires a remedial clinic. The latter will be provided for at the new open-air school. Ilford lacks general hospital facilities. There is, however, an emergency hospital with 64 beds maintained by voluntary subscriptions and patients' fees. The governors propose to increase the number of beds and to establish an out-patients' department on modern lines. At the present time the corporation have an arrangement with Queen Mary's Hospital, Stratford, for the operative treatment of both pre-school and school-children suffering from tonsils and adenoids, and when the extensions of the Ilford Hospital are completed this work will be undertaken in the district. The new maternity home admitted 454 women as compared with 383 in 1926, and has an antenatal clinic open twice weekly. Dr. Everard Williams has been appointed consultant obstetrician. A table shows that there was 1 death from syphilis, 1 from locomotor ataxia, 34 from general paralysis of the insane, and 2 from aortic aneurysm. If all these are regarded as syphilis they make up a death-rate of 0·35 per 1000 from that cause.

There is one whole-time dentist who gives one whole morning weekly to the maternity and child welfare work, one afternoon every fortnight to tuberculosis patients, and the rest of his time to the school work. About 57 per cent. of the children inspected by him were found to need treatment, but only half accepted the treatment facilities offered.

Aberdeen.

In his report on the health of the city for the month of February Dr. J. Parlane Kinloch shows that the health department is taking active steps with regard to immunisation. Thus, during the month 18 of the hospital staff were immunised against diphtheria, 5 against scarlet fever, and 5 against both diseases. Sixty-two in-patients were immunised against diphtheria and 18 against both diseases. At the child welfare centres 106 children were immunised against diphtheria and scarlet fever—at the schools 630 and among out-patients 103. In addition 262 school-children were immunised for diphtheria alone and 127 for scarlet fever alone, while 68 out-patients were protected against diphtheria alone and 12 against scarlet fever. Eighty-seven households from which patients had been removed to the city hospital were visited and the consent of 29 susceptible contacts to immunisation was obtained. Of seven cases of dysentery notified during February six, of which four occurred in one family, were found to be due to the Flexner bacillus and one to the Sonne bacillus.

MENTAL HOSPITAL REPORTS.

Of the two Hampshire *Mental Hospitals*, that at *Knowle* is an old building where a gallant attempt is being made to carry on modern treatment. Re-decoration is gradually overtaking disrepair, and rooms are being adapted for X ray and ultra-violet apparatus. The old farm has been converted into a hospital for the treatment of general paralysis by malaria, and two verandahs have been added for recent cases. 1012 patients were on the books at the end of the year. The recovery-rate was 27·43 per cent. and the death-rate 6·87 per cent. The cause of death was verified by autopsy in 50 per cent. of the total number. There were four cases of typhoid fever during the year, but none of colitis, and the decrease in tuberculosis continued. Of the 14 paralytics treated by induced malaria, two have been discharged recovered, one died of malaria, and three died later; two were unimproved. The remaining six, though unfit for discharge, are now quiet, well-behaved, and able to do routine work Parole was introduced last year and has been extended, and there are open-door and club wards. Basket and chair work have been added to the list of occupations for patients. The farm supplies milk and vegetables, and returned a gross profit of £1500. Seven male and eight female nurses obtained their certificate.

At *Park Prewett* there were 1248 patients at the end of the year, and the records show a recovery-rate of 34·44 per cent. and a death-rate of 6·69 per cent. The general health was good, save for an outbreak of dysentery which attacked nine women. Only two patients are suffering from tuberculosis. Five villas are run on the open-door system and parole is given wherever possible within the estate, but not at present beyond its limits. The dentist visits weekly, and there is a visiting surgeon and an ophthalmologist. A separate block has been opened for private patients, and an operating theatre and bacteriological laboratory will shortly be available. The nurses' home, when open, will fulfil a long-felt want and release accommodation for patients. Eight male and seven female nurses passed their final examination during the year.

The *Wilts County Mental Hospital*, in its report for 1926–27, reports an increase of eight patients, bringing the total to 1176. The recovery-rate was 20·3 per cent. and the death-rate 8·6 per cent. All but two of those discharged had a probationary period on trial, and to 12 of these a money allowance was granted. The villas and annexe are administered on the open-door principle, and a number of patients have parole within the estate and a few outside. The cause of death was verified by autopsy in 71 per cent. of cases; the commonest cause was senility, closely followed by tuberculosis. The institution suffered from a severe epidemic of influenza, with one death, as well as 20 cases of dysentery and isolated cases of mumps, erysipelas, and diphtheria. The Commissioners urge provision of verandahs and a clinical laboratory, and the addition of butter and vegetables to the dietary, as the record of tuberculosis and dysentery is higher than in most institutions. Six female nurses work on the male side; 53 of the staff are certificated or registered. There is a distinct shortage of nurses. Out-patient clinics are conducted by the medical superintendent at the Victoria Hospital, Swindon, and the Cottage Hospital, Trowbridge; the results of the first year's working have been very encouraging.

At *Hellingly*, the *East Sussex County Mental Hospital*, there were 1192 patients at the end of the financial year; the majority of those admitted had a bad prognosis. Nine were epileptics and 10 were general paralytics sent for malarial treatment. Five of the latter showed distinct improvement. News has been received from eight of those discharged after induced malaria during 1925 and 1926. Seven were at work and doing well, though it is perhaps too early to speak of "cure." The total recovery-rate was 10·25 per cent. and the death-rate 7·6 per cent. During the year there was an epidemic of influenza, two cases of scarlet fever, and several of tonsillitis, five of measles, and some 60 instances of scabies. There were only four cases of dysentery. Sixteen operations were performed during the year, and the ophthalmic and dental surgeons have attended regularly. The former saw 271 patients, and the latter 629. Last year the hospital was badly overcrowded, but the completion of verandahs and additions to the nurses' home have remedied this.

617 patients were usefully employed, and raffia, wool-work, and rug-making have been added to the list. Considerable benefit has been derived from the Swedish drill classes for women. Many patients wear their own clothing, and the open-door system has been extended. The medical superintendent feels that the additional risk of escape is more than compensated for by the greater freedom and happiness of the patients. There have been further improvements in the dietary. The committee experience difficulty in securing enough nurses; four male and 15 female nurses passed their final examination, two of the women with distinction. The pathologist supplies an interesting report, including a full review of the malaria-treated paralytics. In addition to routine work for the hospital and county, research has been done on methods of investigation, and eight chronic cases were treated with protein therapy with one improvement.

Institutions for the Mentally Defective.

The *Lancashire and Cheshire Society for the Permanent Care of the Feeble-Minded* presents its twenty-eighth annual report for 1927. It had 325 patients in the institution at the end of the financial year, of whom 220 were adults who had been there for a long time, some of them more than 20 years. They are distributed among nine different houses. The men and boys work at farming, gardening, shoemaking, tailoring, brush and mat making, plumbing, weaving, bricksetting and house painting, and are very keen about and proud of their work. There is urgent need of a few quiet single rooms for girls who have intermittent attacks of excitement; at present such a patient simply has to be transferred. During the year "Noah's Ark," a new building for 50 patients, was completed and occupied, but involved a heavy overdraft and debt. The general health for the year was excellent, save for three mild cases of chicken-pox and a mild but prolonged epidemic of scarlet fever. There is one consumptive girl—only the third in the whole record of the home—and she is being nursed in a special little shelter in the grounds. The dietary was alterated to approximate closely to a vegetarian one, and the visiting commissioner felt anxiety about the lack of protein. The managers maintain that the reduction in meat has resulted in a great diminution in the number of common colds and bronchial affections, and that the gain in weight was adequate. The experiment appears, indeed, to be turning out satisfactorily.

The *Royal Albert Institution, Lancaster*, had 800 residents at the end of the financial year. The medical superintendent recognises that tuberculosis is the special enemy of the defective, and for this reason occupation classes are held on the verandah whenever possible, and a new verandah has been added to the girls' wing. Artificial sunlight apparatus has been installed. A new water service has been laid down, and a new sanitary block added. The usual occupations have been carried on during the year, and chair-caning classes and papier-maché moulding have been started. School gardening has been particularly successful in interesting the children. A number of the nurses have been successful at the R.M.P.A. examinations.

Both these reports are beautifully illustrated, and both institutions make an earnest appeal for funds.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 24TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 342 (last week, 359); scarlet fever, 1815; diphtheria, 1323; enteric fever, 45; pneumonia 1898; puerperal fever, 31; puerperal pyrexia, 98; cerebro-spinal fever, 12; acute poliomyelitis, 8; acute polio-encephalitis, 2; encephalitis lethargica, 36; continued fever, 1; dysentery, 6; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on March 27th–28th was as follows:—Small-pox, 5; scarlet fever, 1594; diphtheria, 2507; enteric fever, 32; measles, 1546; whooping-cough, 136; puerperal fever, 15 (plus 13 babies); encephalitis lethargica, 70; other diseases, 33. At St. Margaret's Hospital there were 15 cases of marasmus, and 12 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were 2 (0) deaths from small-pox, 2 (2) from enteric fever, 166 (99) from measles, 4 (0) from scarlet fever, 51 (16) from whooping-cough, 44 (7) from diphtheria, 55 (14) from diarrhœa and enteritis under two years, and 135 (19) from influenza. The figures in parentheses are those for London itself. The 2 small-pox deaths were assigned to South Shields and Aberdare. Of the 67 fatal cases of measles outside London 9 were reported from Sheffield, 7 from West Ham, and 4 each from Willesden, East Ham, and Brighton; while the figures in Glasgow and Dublin for the same week were 16 and 7. The number of stillbirths registered during the week was 276 in the great towns, including 55 in London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. G. E. Hamilton is placed on the Retd. List with the rank of Surg. Capt.

Surg. Lts. (D) to be Surg. Lieut.-Comdrs. (D): D. C. Eglington and E. C. Bevis.

Surg. Comdr. A. C. V. Green to *Danae*.

Surg. Lt.-Comdr. (D.) D. Paterson to *President*, for P.G. course.

Surg.-Lt. E. R. P. Williams to *Douglas*.

ROYAL ARMY MEDICAL CORPS.

Capt. J. A. Crawford to be Maj.

Temp. Capts. (Dental Surgs.) C. J. Pellow and H. E. Hayes (Temp. Flight Lt., R.A.F.) relinquish their commns.

Lt. J. M. Johnston resigns his commn.

ARMY RESERVE OF OFFICERS.

Maj. W. S. Crosthwait, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capts. (Prov.) W. Simpson and G. F. Keatinge are confirmed in their rank.

Lt. F. R. Sanford to be Capt.

ROYAL AIR FORCE.

Flight Lt. G. E. Church is granted a permanent commission in this rank.

The undermentioned Temporary Lieutenants (Dental Surgeons, Gen. List) are granted temporary commissions as Flying Officers on attachment to the R.A.F. H. E. Glover and G. M. Titterington.

Flight Lt. E. Alston (temp. Capt., Dental Surgeon, Gen. List) relinquishes his temp. comm. on resignation of his Army commission.

Hospital Saving Association.—It is officially announced that £28,370 has been distributed to coöperating hospitals for the last quarter of 1927, which exceeds by £6000 the distribution for the same period of the preceding year. The Association makes annual grants also, and now that the membership exceeds 400,000 it is believed that there will be a substantial surplus for this purpose at the end of the financial year on July 31st.

Progress of Royal Northern Hospital.—At the annual Court of Governors it was stated that 5370 in-patients were treated last year, an increase of 3046 on 1914. The out-patients' attendances were more than a quarter of a million, nearly three times as many as in 1914. The Board are considering the practicability of providing a separate block of wards for middle-class patients, their experience with the existing private wards having shown them the need for self-supporting accommodation of this kind. The hospital has a debt of over £81,000.

Correspondence.

"Audi alteram partem."

ABSCESS OF THE BRAIN.

To the Editor of THE LANCET.

SIR,—Your leading article of March 10th and Mr. Miles Atkinson's letter in your issue of the 24th raise several interesting and important questions. Cerebral abscess presents itself in many forms, and any grade may be met with from an acute purulent encephalitis to a completely isolated thick-walled abscess constituting an almost solid tumour. Further, in almost any form the abscess may be complicated by extradural suppuration, sinus thrombosis, and meningitis. Few generalisations, therefore, can be made in regard to diagnosis and treatment which would be applicable to all cases. They can, it is true, be divided broadly into several groups which, however, necessarily overlap considerably, and a line of treatment suitable for one kind of case may be quite wrong when applied to a case in a different category. The great discrepancy between Macewen's results and those of all other surgeons is largely, I think, to be explained on these grounds. A perusal of Macewen's classical monograph (1893) brings out the fact that he was dealing with one particular group of cases—namely, definitely encapsulated abscesses with a long history. The average duration of the illness before operation was, in the 12 cases in which it is stated, no less than 70 days. Cases XXV. to XL., in the common situations—namely, temporal, cerebellar and frontal, were all of this kind, and of these 16 patients, 12 recovered, giving the extremely low mortality of 25 per cent. With the exception of the very long-standing, inactive, thick-walled abscess which can, and should, be shelled out whole, these 16 cases belong to the most favourable class. Further, no one, I think, who reads the detailed account of these cases can help being impressed with the meticulous personal attention to detail, characteristic of Macewen, which is evident throughout, and which doubtless contributed in no small measure to his successful results.

It would lead me too far to take up all the points raised in your leading article. Mr. Atkinson is undoubtedly right in stating that neither a rapid rise of intracranial pressure nor a rapid onset of papillœdema is characteristic of abscess formation. Headache and drowsiness (perhaps "apathy" is a better description) are the non-localising symptoms which in my experience are almost constantly and characteristically present. The most important point however, raised by Mr. Atkinson is the stage at which operation should be undertaken. I should never, myself, undertake to explore for abscess in the absence of any localising signs. I should also be very sceptical about accepting a statement that no localising signs were present in any given case. "Silent areas" are only relatively silent, and an area which has no message for one observer may be eloquent to another.

One further point relates to "hernia" of brain, which is so often confused with "fungus." The two are in reality totally distinct. Hernia cerebri means the protrusion of normal brain through an opening in the bone and dura, such as is deliberately brought about for the relief of intracranial pressure; a fungus cerebri is a protruding mass of strangulated necrotic tissue, indicative both of sepsis and of unrelieved intracranial pressure. Its appearance after the opening of an abscess is the consequence, and not the cause, of the meningitis which so often determines the fatal issue.

I am, Sir, yours faithfully,

PERCY SARGENT.

Harley-street, W., April 2nd, 1928.

WOMEN MEDICAL STUDENTS IN LONDON.

To the Editor of THE LANCET.

SIR,—Notwithstanding the action of certain medical schools in closing their doors to women it may be expected that the number of women medical students will at least be maintained. So far as it is possible to calculate on the rather inadequate data available about 100 women annually start in London the study of medicine. Of these the Royal Free Hospital can receive, I believe, between 40 and 50, while University College Hospital limits itself to 12. There will therefore probably be a balance of some 50 women to be provided for. One solution is that a new school of medicine should be founded, perhaps one which by its constitution received both women and men. If it is true that men on account of athletics or for other reasons prefer not to go to a school at which there are women provision will at least be made for those women who cannot be received at the Royal Free Hospital and who cannot because of their sex go to the other hospitals with schools. It is difficult to believe that London could not provide the clinical material and learned and skilled teachers for such a foundation. At any rate, I venture tentatively to put forward this suggestion in the hope that it may elicit support or criticism or alternative schemes. Its excuse must lie in the patent problem that in a year or two there will be a demand on the part of women medical students in London for twice as much accommodation as will be provided.

I am, Sir, yours faithfully,

E. D. MACNAMARA.

Harley-street, W., March 31st, 1928.

NASAL OBSTRUCTION AS A CAUSE OF DEAFNESS.

To the Editor of THE LANCET.

SIR,—In your very interesting and timely leading article in a recent issue (Feb. 4th, p. 241) the causes of deafness were enumerated, but one possible cause very relevant to the present issue was omitted. About the year 1900 I noticed that if I swallowed while I held my nose closed I produced both deafness and tinnitus. I concluded that a person with nasal obstruction, when swallowing, would reverse the normal process and abstract air from the tympanum. I discussed the point with the distinguished otologist to whom I send serious cases, and he agreed that at least it was possible to empty the tympanum by swallowing. I suggest that the chief object of the cavities, accessory to the tympanum, is to facilitate movements of the drum, by acting as reservoirs into and out of which air can pass from and to the very limited chamber forming the tympanum proper. The unoccupied space in the outer labyrinth, formed by these communicating chambers, is minute when compared to the extent of the lining membrane within it. Swelling or effusion from this membrane will, in addition to impairing the suppleness of the tympanic apparatus, proportionately reduce its capacity and cause the expulsion of air. The disappearance of the swelling or effusion will then produce a partial vacuum unless atmospheric pressure is restored by the normal method. Should any permanent reduction in capacity result, the effect of a subsequent attack will be thereby exaggerated. I regard this explanation as more in accord with the clinical history of the class of case I am referring to, and indeed with physical laws, than that absorption of air with the production of a minus pressure should occur, apparently at intervals.

At the time referred to, three remarkable cases convinced me that, whether my hypotheses were correct or not, nasal obstruction as a cause of deafness was frequently overlooked.

The first was a wealthy man who had consulted aurists in London, Berlin, and Vienna. He consulted me for headache, which I attributed to pressure within the nares. I removed an enlarged middle turbinal and cauterised the

mucous membrane freely. The headaches ceased ; but the point of interest is, that he told me one day, that standing by the side of an engine he had heard it letting off steam, and that previously he had been unaware that it made a noise in doing so, and he wrote to me at a later date that he was attending concerts regularly, as he found that by sitting in the front row he could follow the music.

The second case was that of a violinist, whose nose ran so that the secretion dropped on the violin as he played. Treatment involved restoring the nasal passages. He was a foreigner, young though distinguished, and one day he came into my room in a very excited state. In fact, I thought he was going to embrace me. The explanation was that he had been deaf in one ear since boyhood, which I did not know, and he found that the hearing was returning.

In the third case treatment was directed to restoration of hearing. A woman, about 50, failed to understand me, even when shouting into her ear. The deafness was comparatively recent, and was exaggerated by an illness from which she had recently recovered. She had complete nasal obstruction, and I was anxious to see the effect of its removal. She decided, before submitting to treatment, to consult a then celebrated aurist, who vetoed the treatment. A few months afterwards, however, she decided to place herself in my hands. When she did so there was no substantial change in her hearing. About six months later it had practically returned to normal, and I lost sight of her.

The fourth case I will quote is the last of a long series I have since treated. A woman, aged 52, consulted me on Sept. 21st, 1927. She could hear a loud voice at a distance of 1 foot. She informed me that she had been getting deaf for about ten years, and had been last treated two years before, and since then her hearing had remained stationary. The treatment apparently consisted of catheterisation. I found a general œdematous, almost polypoid condition of the mucous membrane. Her respiration is now perfect. She recently came to report progress, and though her hearing is not normal, she can repeat a moderate whisper at 8 feet.

In practice it is impossible to eliminate possible contributory causes. For example, I frequently cauterise the inferior turbinal to its extreme posterior end, and at a subsequent visit remove part of the fringe of mucous membrane along its lower border or its posterior end. The cauterisation renders the subsequent procedure practically bloodless. The effect is that, in addition to freer respiration, a horizontal scar is produced which may drag on the anterior wall of the tube. I also teach my patients a method of inflation which I believe obviates the risk of over-inflation in one ear. I once heard an oculist utter the dictum : " Never be the first to pass a probe down the lacrymal duct," and I have never since passed a Eustachian catheter if I could avoid it. With the patient in front of me I instruct them to raise the pressure in the post-nasal space until air enters one tympanum, but to cease all effort immediately it does so. I then get them to place the tip of the thumb on the edge of the tragus, so as to bring its margin into contact with the opposing surface, and thus close the external meatus. Slight pressure on the tragus wlll then raise the pressure on the outer side of the drum and effectively prevent the further entrance of air into the tympanum. With the inflated ear thus protected I instruct them to force air into the other ear, if possible, but to cease all effort again immediately the air is felt to enter. Preliminary nasal irrigation enables a large proportion of obstinate cases to inflate.

Obstruction is a very relative term, and patients may suffer from it at night only, though such obstruction would not per se cause deafness. Frequently when I have, from the symptoms described, diagnosed what I may term " nocturnal obstruction," patients have been previously or subsequently assured, by men whose opinions I highly respect, that no obstruction was present. It was true that they had free nasal respiration when examined, yet they snored at night, woke up with a dry mouth, often with a nasty taste, and suffered from chronic pharyngitis or laryngitis, and the improvement in general health which follows treatment resulting in the disappearance of these symptoms is very remarkable. To me it remained a very interesting enigma until attention was drawn to the ill-effects of oral sepsis. I have had many patients whose tonsils had been removed with little benefit, whereas the subsequent establishment of nocturnal nasal respiration gave the desired result. I am not questioning the removal of septic tonsils, but maintaining that this condition, or that of pyorrhœa, is frequently one focus only, though it may be the most important focus in a regional infection, the cause of which is allowed to persist. Unfortunately, the treatment may require a number of visits extending over a considerable period. Over-cauterisation or removal of tissues is so easy, whereas the provision of the minimum space required, and its provision with the minimum destruction of tissue, necessitates the careful re-examination and consideration of the case at each visit, and such intervals between the visits that the effects already obtained may be assessed. In a large practice I believe charts to be indispensable. A few strokes or curves on it necessitate accurate detailed knowledge as well as knowledge of the nares as a whole. They can be made in a few seconds at the completion of the treatment or examination, and at any subsequent visit give the surgeon *who made them* a vivid conception of the original condition and any treatment he adopted, while the result of the treatment is before him.

I may add a method I adopt to avoid injuring the bone when cauterising. It is practically invariably successful. The cautery is raised to the temperature at which it adheres to the mucous membrane, allowed to cool, and then moved to and fro. The extent of movement gives an accurate idea of the depth of tissue between it and the bone.

I am, Sir, yours faithfully,

H. MACNAUGHTON JONES.

Swiss Cottage, N.W.3., March 24th, 1928.

HYGIENE AT THE ROYAL HOSPITAL SCHOOL, GREENWICH.

To the Editor of THE LANCET.

Sir,—In answer to Dr. Percival M. May's letter of March 23rd in your issue of March 31st, may I say that the condensation of my remarks by the reporter has made the statement attributed to me stronger than it was.

As to overcrowding in the school sleeping quarters, I formed my opinion by the scale diagram on page 34 of Dr. Dudley's first report [1] showing beds within 1 ft. 9 in. of each other in batches of nine, and, though the ingenious arrangement of head and tail adopted minimised the risk to some extent, I still consider them overcrowded. In his later report [2] Dr. Dudley says the average floor space is 40 sq. ft. per bed, and the space between beds varies between 1 ft. 9 in. and 3 ft. 9 in., the average being 2 ft. This I took to mean that the bed plan shown in the first report (referred to above) was still the prevalent arrangement. If so, and indeed in any case, where beds are only 1 ft. 9 in. apart I consider there is overcrowding—not severe but quite definite. Such diverse authorities as the Royal Commission for Improving the Sanitary Condition of Barracks (1861) and the Board of Education Buildings Regulations for Secondary Schools, 1914, p. 14, both ins'st upon 3 ft. between beds, and in the first instance 60 sq. ft., and in the second 65 sq. ft. of floor space and 700 cubic ft. per occupant. Especially are these conditions necessary in dormitories such as those at Greenwich, where exceptionally large numbers of boys (70 to 126) sleep in the same dormitory.

My quotation of the attack rate of rheumatic fever at Greenwich as 6 per 1000 per annum is from Table VIII., " Relative Incidence," p. 44 of Dr. Dudley's second report, No. 111. This table gives the actual morbidity per 10,000 per annum from Greenwich as 60. No date is given, but the entry follows immediately after Shotley, 1917–24. I judged it to refer to a number of years' experience. I note elsewhere in the report it is given as 6 per 1000 in 1920 and 2 per 1000 in 1921.

[1] Medical Research Council Special Report, No. 75.
[2] Special Report, No. 111, p. 1.

I merely wish to show that I did not carelessly misquote Surgeon-Commander Dudley's work which I admire, and I should be very sorry indeed if anything I had said could be construed to mean that those responsible for the health and care of the boys were lacking in the necessary vigilance or were behind the times.

In my report on acute rheumatism I say "that probably the high rate is largely due to the care in recording those cases which being mild in character might have escaped record or been recorded as 'subacute' elsewhere."

I am, Sir, yours faithfully,

J. ALISON GLOVER.

Netherhall-gardens, N.W., April 3rd, 1928.

DISEASE IN THE WEST INDIES.

To the Editor of THE LANCET.

SIR,—During a recent visit to the West Indian Islands I had the good fortune to get into intimate touch with their educational systems, and it may interest your readers to learn that on these islands one finds no cases of rheumatic heart disease, no orthopædic trouble, and no children who are deaf and dumb. The large amount of sunshine and warmth in the West Indies may explain much of their freedom from diseases with which this country is so greatly troubled, but it will not help to explain why these diseases are on the increase with us. Were infection responsible, even in part, for the spread of rheumatic fever, one might feel justified in expecting the warmer atmosphere to be more congenial to the spread of the "specific" organism. The food of the children consists mainly of fruits, vegetables, peas and ground provisions, together with a fair quantity of milk, mainly from the goat. Fruits and vegetables are grown on a soil well supplied with lime, the islands being of coral formation, and the children as a consequence are able to obtain plenty of lime for their blood and bones.

I have long been trying to emphasise the fact that rheumatic heart disease occurs only in one type of child—namely, that which dislikes or does not obtain milk with its high lime-content, but with a perverted appetite partakes of acids in the form of vinegar, sauces or pickles. Some support is lent to my contention by the state of things to be found in the West Indies.

I am, Sir, yours faithfully,

G. ARBOUR STEPHENS.

Swansea, March 26th, 1928.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Glasgow Cancer Hospital.

AT the recent annual meeting of the Glasgow Cancer Hospital Sir George Beatson said that he knew enough of the disease to say with confidence that it began as a local malady and, if dealt with early, could be successfully removed by surgery. For practical purposes this is generally accepted and verified. But it leaves the real origin of the disease still a mystery. The hospital, said Sir George Beatson, was the only cancer research centre in Scotland, in fact the only anticancer centre in Scotland, and, if radium was found to be of use, they would like it to become the distributing centre for radium emanation. A large question is here raised. Much radium work is being done; but I gathered from a recent talk with a radiological expert that some of it is mere "pottering," just as in the case of ultra-violet. In the whole field of radiation-therapy—X ray, ultra-violet, deep-cancer therapy, radium, &c.—one variety of radiation runs into another, and the only safety is to see that any fresh developments are controlled by men skilled in the use of all forms of radiation. Otherwise we mayget X ray or radium light-heartedly applied to a suspected rodent ulcer on the temple without thought as to what may happen to the eye and its structures. And the craze for ultra-violet is crying out for some reasonable control and criticism. But all this is only another way of emphasising the great and unknown agencies it is now our privilege to have and to investigate. Everyone sympathises with Sir George Beatson's wish for more and more research.

At the same meeting Sir John Gilmour, Secretary of State for Scotland, as head of the Board of Health and responsible for the time for the direction of that department, wanted to say emphatically that, whatever advances were to be made in Government hospital policy, one fundamental thing was the voluntary principle. He hoped that there was a measure of coördination and cöoperation between the large number of hospitals in Glasgow, so that overlapping might be avoided. One knew what a tremendous strain it was upon the resources of the citizens to maintain these great institutions, and if the voluntary principle was to succeed, it could only do so if there were no overlapping and unnecessary calls upon the community.

The Friesian Cow.

In the course of the coming generation it is to be hoped that the consuming community will begin to understand the importance of milk records as a method of increasing the food-supply. For the present this seems to excite any interest only in the stock-breeders; but surely the knowledge deserves wider appreciation. For instance, the British Friesian Society state that Eldad Meilbloem, one of the British Friesian cows in the pedigree herd of the West of Scotland Agricultural College at Kilmarnock has, for the second time in her career, exceeded the 2000-gallon yield of milk within the year. This noted animal is also one of the 27 British Friesian cows to produce in one year milk containing the equivalent of 1000 lb. of butter, and when it is realised that a 2000-gallon cow must average 4·25 per cent. butter-fat over her lactation period to be regarded as a 1000-lb. butter cow, the merit of such a performance can be fully appreciated. The details of this cow's story are given and they are a marvel among lactation histories. The marvel might appeal to those pessimists who foretell the failure of food production to keep pace with population. While, under natural selection, a wild cow gives only 150 gallons a year, cows under scientific selection may give 2000 gallons, so increasing *this* food-supply more than ten times! And this is only a mere hint of what is possible in this minor section with the knowledge we already have. Yet the Kilmarnock College has, in the past, had many a difficult year to face.

Edinburgh Maternity Hospital.

Dr. Nasmyth made an admirable appeal at the annual meeting of the Simpson Memorial. In 1927 the number of deliveries in the hospital was 2094—a record. Taking the total of indoor and outdoor cases last year the gratifying fact was disclosed that 38·6 per cent., or more than one-third of the births of Greater Edinburgh, took place under the supervision of the staff. The antenatal clinics continued to grow in popularity and usefulness. In 1927 there were 10,002 visits. The postnatal clinic, now in action, attracted over 1000 visits in the first 12 months and the results had been most satisfactory. During the year 83 nurses and 287 students had been trained. Mrs. Burnett Smith (Annie S. Swan) said that the persistence of the hardy spirit of independence was proved by the pathetic readiness of the great majority of the patients to pay the modest fee asked from those who were able to pay. Dr. Haig-Ferguson emphasised another point—that their duty as directors was to provide a maternity service for the eastern counties of Scotland in an undersized, somewhat obsolete and out-of-date building, incapable of adequately overtaking its important function. Why was the hospital the same structurally as it was 50 years ago, in spite of the greater work done? It was not the fault of the directors, but it was due to the apathy of the public, who could not be raised to any enthusiasm about a maternity hospital. The public had failed to

rise to what they ought to do. This is a serious statement coming from the chairman of the Central Midwives Board for Scotland, himself one of the most distinguished in the long line of Edinburgh gynæcologists. In this special section of hospital it looks as if, for one reason or another—over-division of interests or genuine public apathy—the so-called "voluntary principle" were nearing its limit. But the movement towards effective "coöperation" among hospitals, voluntary (pay and non-pay) and official, has really begun. Edinburgh is never in a great hurry to move; but, as the recent developments at the Royal Infirmary prove, she goes far in the end, and I have no doubt of the big future of the Simpson Memorial as a factor in the larger schemes now coming to clearer definition in the administrative minds.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Recruitment of the German Army Medical Corps.

BEFORE the war the German Army Medical Corps was mainly recruited from pupils of the Army Medical College. This institution was run in connexion with the medical faculty of Berlin University, the students attending the same lectures as their civilian contemporaries and passing the same examinations, though they had to attend special classes at the College as well. Like other students, they had to serve six months as privates in order to comply with the Conscription Act. The condition of entry to the Army Medical College was that the military students who enjoyed study free of charge and received free board and lodging in the College were obliged to serve one year as medical officers with the army or navy for every term of study. When the German army was reduced under the Treaty of Versailles, the Army Medical College was abolished and the Corps has since been recruited from civilian doctors. In spite, however, of the overcrowding of the profession, only a very few medical men have applied to enter the army, so there has been some difficulty in filling vacancies. The reason for this is said to be the fact that the army authorities have imposed on applicants the condition that they should serve for six months as private soldiers in order to learn military life and exercises, a condition, of course, not very attractive to men who have already qualified as medical practitioners. The medical papers report that the Government intends to revive the former system in an altered form. It proposes that medical students should be trained at the public expense provided they accept the obligation of serving one year in the army or navy for every year of study. Their position would be that of soldiers ordered to study medicine, as was the case with the students of the former Army Medical College, who, although not wearing uniform, were always under military rule. In this manner there would be no necessity for them to do ordinary military service after qualification since they would get the required experience as young medical students. The medical journals object to this proposal. They say that as the profession is greatly overcrowded and many medical men have the greatest difficulty in earning their livelihood, the army authorities could get all the staff they require if only they would make the military career more attractive, especially by withdrawing the odious demand for ordinary military service as privates. Free study at the public expense would increase the number of medical students, and many of them, after having served the prescribed time in the army, would become civil practitioners, thereby making the position of the profession worse. As the total number of medical officers in the army is only 297 and in the navy 98 there should be no difficulty in filling the few vacancies occurring every year, even if the above stringent measures are not taken. The army authorities need do no more than apply to the Leipziger Verband, which is certainly prepared to propose an adequate number of medical candidates fit for the service in the Army Medical Corps.

Statistics of the Medical Profession.

In 1927 there were 47,338 medical men registered in Germany—i.e., 7·45 to every 10,000 of the population. This number has constantly increased, as there were 44,351 (7·10 for every 10,000) in 1926, 41,650 (6·67) in 1925, and 36,156 (5·99) in 1921. In 1913, before the war, when the territory of Germany was still greater, there were 34,136 practitioners—i.e., 5·11 for every 10,000 people, whilst the proportion worked out at 4·92 per 10,000 in 1901. There has thus been an increase of 50 per cent. or more. Eighty-four medical students matriculated for every million of the population in 1881; this number increased to 136·2 in the period 1881–1910, to 210 in 1911–14, and reached its maximum with 252 to every million in 1921. Then followed a reduction to 133 in 1925. The number of qualifications was 823 in 1910, rising to 1242 in 1913, and reaching its maximum (3882) in 1914, when medical students took a so-called emergency examination. In 1918 only 849 diplomas were granted, whilst the number increased to 3082 in 1923 and had decreased to 2004 by 1926. For every 10,000 inhabitants there are now 14·9 medical men in Berlin.

The number of women students was on an average 733 in the period 1911–14, 1538 in 1915–18, and 2077 in 1919–20; it decreased to 1304 in 1926. In 1927 there were 2078 qualified medical women, as compared with 195 in 1913. They amounted to 4·4 per cent. of the profession. Only 149 women doctors reside in places having under 5000 inhabitants and 69 of these are married to local practitioners; country practice is obviously disliked by medical women. Of the medical men 69 per cent. are general practitioners, while 31 per cent. describe themselves as specialists; the comparable figures for women are 71 and 29, so there is only a small difference between men and women in this respect.

Dr. Prinzing, of Ulm, who has recorded these figures, is of opinion that seven medical men would be sufficient for every 10,000 inhabitants, and that they would be able to earn their living. It is found impracticable to limit the number of medical students by legal action, and although an appeal to young men to abstain from medical study has met with some success it is suggested that examinations should be made more difficult, to discourage them from entering the profession.

Campaign against Malaria in Italy.

Before the Berlin Medical Society Dr. Celli-Frentzel, wife of the late Prof. Celli, of Rome, who did excellent work in combating malaria, recently read a paper on the methods and results of the Italian campaign. Formerly, she said, about 22,000 people died in Italy annually from malaria, but they had managed to reduce the death-rate to 15,000 in 1900 and to 2000 in 1914. After the war the death-rate again increased to 11,000, but it is now falling. The principal measures taken are draining of the ponds, destruction of anopheles, planting of eucalyptus, and construction of waterworks. The houses in the malarial districts are protected by wire netting and the malaria patients are isolated. Prophylactic administration of quinine on a large scale to the population, including school-children and casual labourers, is, she considers, of great importance.

A campaign against accidents has lately been carried out in Berlin under the auspices of the sick-clubs, the insurance institutions under the Workmen's Insurance Act (Berufsgenossenschaften), and the Berlin police. In 30 different places evening lectures have been delivered on avoidance of accidents in the street, in factories and at home, and on first aid. These lectures were illustrated by films and were well attended.

At the Berlin Medical Society Prof. Bruno Pribram recently demonstrated a woman who complained of a constant chirruping noise in her head. She was at first believed to suffer from hallucinations, but on

auscultation the noise was indeed detected, and was eventually traced to an aneurysm of the occipital artery. After ligature of the aneurysm the noise ceased and the patient was cured.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

"*Chiropractic is Doomed.*"

THE author of this cheering pronouncement is none other than Mr. B. J. Palmer, the head of the million dollar Palmer School of Chiropractic at Davenport, Iowa. That is if we may believe the report of his speech on Feb. 26th last at Philadelphia, published in the *Pittsburgh Medical Bulletin*. Mr. Palmer complained that his followers were practising not chiropractic, but medicine. "During the last year," he said, "I have been in every State in the Union, and this condition exists throughout. My ideals concerning chiropractic were shattered. Chiropractic is doomed." The point of his distress lies in his recognition that if other methods of healing than the magical adjustments of the spine are employed by chiropractors, then State legislators may reasonably require that chiropractors should have an elementary knowledge of the "basic sciences." Says Mr. Palmer, "I do not propose to lose my good money in fighting against sound arguments."

Invention.

An ingenious device for the localisation of metallic foreign bodies in the tissues has been reported by Dr. M. Wright, of Philadelphia. Two sterile metal filaments, separated by only a small interval at the end, are introduced through a small incision. The site of the incision is of course determined by previous X ray examination. When these two points make contact with any metallic object, an electrical circuit is completed which lights a small bulb in the handle of the instrument. The filaments are provided with a hook to remove such an object as a broken needle when localised. The instrument is illustrated in the current number of the *Journal of the American Medical Association*.

New Research Foundation.

A new research foundation, privately financed, but in charge of a committee of prominent New York physicians, has established headquarters at the New York Academy of Medicine. A series of researches into disorders of the nervous system has been planned, the first problem being a study of Encephalitis Lethargica. It is the intention of the Matheson Survey to send a trained epidemiologist to wherever a group of cases may present itself. He will coöperate with local forces in studying the ætiology of the disease.

CONTRIBUTORY SCHEMES.—The contributory scheme in aid of Worcester General Infirmary is a distinct success. The number of contributors in the city exceeds 10,000, notwithstanding that at the last census the population had not quite reached 50,000; in the county the number is 7000. The second year of the Ipswich Contributory Scheme produced in the borough £15,384, an increase of £1235. For the whole county of East Suffolk the amount raised was £26,500, an increase of £3500.—The Governors of the Kidderminster District General Hospital have decided not to establish a contributory scheme, on the ground that such funds are "a violation of the voluntary principle," that the hospitals which adopt them "offer benefits which they may find it difficult, and sometimes impossible, to provide," and that contributors who believe that they have made a contract for treatment are likely to be disillusioned.—Some of the hospitals in the neighbourhood of Birmingham are nervous about what they consider to be the "poaching" of the recently started Birmingham scheme, and the West Bromwich and District General Hospital, which is very close to Birmingham, has issued a poster warning its supporters that no advantage in the way of treatment is to be obtained by joining the scheme.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

SHOPS (HOURS OF CLOSING) BILL.

THE Shops (Hours of Closing) Bill was considered by Standing Committee A of the House of Commons on March 27th. Mr. ELLIS DAVIES presided.

On Clause 1 of the Bill, which provides for general closing hours of 8 P.M., with 9 P.M. on one day in the week, Mr. T. WILLIAMS moved an amendment to make the respective hours 7 P.M. and 8 P.M.

Sir PARK GOFF, who was in charge of the Bill, resisted the amendment.

Miss MARGARET BONDFIELD, in supporting the amendment, said that longer hours of opening produced over-fatigue, due not only to the actual work but to the hanging about which was of itself productive of very great fatigue.

Sir W. JOYNSON-HICKS (Home Secretary) said that the question under discussion went to the root of the Bill, and if the amendment was carried it would go a long way towards wrecking the measure. The Bill was a very good Bill, and he wanted to get it through with general assent.

The amendment was withdrawn.

The Supply of Articles Required in Illness.

Miss ELLEN WILKINSON moved an amendment to omit the provision permitting the supply of an article after the closing hour when reasonable grounds existed for believing that the article was required in case of illness. As the clause was drawn she thought it left the door open for a great deal of abuse of what might otherwise be quite a wise provision. The only cases which this clause might be held to cover were cases of sudden emergency, not cases of ordinary illness which were dealt with in the ordinary way. The phrase "reasonable grounds" in an Act of Parliament opened the door to all sorts of abuse, and proper administration was made very difficult. There was hardly an article in a grocer's shop that one could not say was needed in case of illness. She was perfectly willing that there should be some means of securing any kind of medicine or article really wanted in an emergency, but these, she argued, were already dealt with in paragraph 1 (*f*) of the First Schedule.

Sir PARK GOFF said the effect of this amendment would be to prevent shopkeepers supplying articles in case of illness except where those articles happened to be medicine or medical and surgical appliances. That was provided for in the First Schedule, and he did not know what had prompted this amendment. The Departmental Committee did not consider this particular point. This suggestion for articles to be supplied in the case of illness was by no means a new one, and they were only reproducing a provision in the Act of 1920. There was an entirely similar provision in Section 4, Subsection (7) of the Act of 1912, and there was no evidence whatever that any abuses had arisen in regard to the provision he had just mentioned. There might be articles which were not sold by chemists which were really necessary in cases of illness, such as ice, to be purchased from the fishmonger. It seemed desirable not only from the point of view of the public generally but from the point of view of necessitous cases and accidents that this point should be carefully considered.

Mr. MACQUISTEN said that this was a thoroughly heartless amendment. Could there be anything more cruel when somebody required in a case of illness a light meal or even a dose of some sort of medicine than to suggest that it should be possible for a person to be shut off and prevented from getting what he required?

Sir W. JOHNSON-HICKS said that he would undertake to see that it was made clear that when a shop was open for the supply of articles required in cases of illness it was not to be used for selling anything else.

The amendment was withdrawn.

Clause 1 was ordered to stand part of the Bill.

HOUSE OF LORDS.

THURSDAY, MARCH 29TH.

TETRA-ETHYL IN MOTOR SPIRIT.

Lord BUCKMASTER asked (1) what was the constitution of the committee set up to inquire into the danger arising from the use of lead tetra-ethyl in motor spirit; (2) why the committee were not sitting in public; (3) when the report was anticipated, and moved the following resolution:—

"That serious warning should at once be issued by the Minister of Health as to the possibility of danger of the use of tetra-ethyl motor spirit."

He said that he desired to recognise the wisdom and the liberality of the Ministry of Health in asking Prof. Bak

to serve upon the committee. Prof. Baker had informed him that owing to ill-health he could not sit at present, but he (Lord Buckmaster) hoped that Prof. Baker's place would be taken by a man equally distinguished and equally independent. Whatever form the committee took the public were entitled to know what the evidence was. He hoped that this inquiry would be prosecuted energetically. The matter was far too grave to allow of Government Departments reclining in Olympian ease while people might be suffering whom it was the business of those departments to protect. Although this spirit had been in use for a considerable time, and was advertised in this country more than nine months ago, no form of warning had been issued to any person who was compelled by his occupation to use it. No answer had ever been given to the grave and serious reports which he had read to the House on the last occasion from a professor of chemistry at Cambridge University, and from the President of the Chemical Society.

A Medical Man's Information.

Since that time further information had come into his hands. He had received a letter from a man who was M.D. of London University, and held the Diploma of Public Health of Cambridge. This gentleman said that he had read with interest what had taken place, and went on to say:—

"On Dec. 15th last there was submitted to me for examination parts of a car which had been run some 3000 miles on ethyl petrol obtained from garages in this country. The deposits proved to contain over 50 per cent. of soluble lead, and in view of the dangerous nature of this material I immediately communicated the fact to our Member—the Right Hon. Sir Philip Cunliffe-Lister—and, as arranged, I interviewed the petrol superintendent of the Board of Trade, and Mr. J. L. Jeffery, of that Department, came to my laboratory, examined the parts, and confirmed the chemical findings. He informed me that he would minute his report to the Home Office that same day, and suggested I should invite their representatives to do, as he had done, and 'see for themselves.' In accordance with this suggestion, I telephoned to the Home Office, and was informed by their Chief Medical Inspector of Factories that I should put my information into writing for their consideration, and further, that they could not move in the matter save only upon such written information. Astonishment was expressed at the fact that ethyl spirit was obtainable at garages."

He (Lord Buckmaster) really could not think that something that was known to the world was unknown to the very department whose business it was to control it. However, such appeared to be the case. On Dec. 22nd this confiding gentleman handed all the facts in writing to the Home Office, and received a printed acknowledgment, but had received no other communication since. Here was another man who by his position was entitled to some consideration, yet nothing had been done. This medical man had written to the *Medical Officer* on Jan. 14th of this year some information which he (Lord Buckmaster) would have thought it was the business of the Ministry of Health to know. This doctor said in the medical journal:—

"On account of the secrecy observed it is not possible to give exact figures as to the number of acute cases of industrial poisoning associated with the handling of this substance in the United States between the autumn of 1923 and the spring of 1925, but the figures available with regard to fatal cases vary from 11 to 16. About 100 non-fatal cases are also known to have occurred. Cases of serious poisoning were reported elsewhere."

This doctor also pointed out what was undoubtedly true—that one of the most terrible effects of this poison is that death is preceded by one of the most hideous forms of insanity. He believed that those figures were challenged. In the interests of science for great causes men's lives might and should be sacrificed; but not for this purpose, which was to enable somebody who normally exceeded the speed limit by 100 per cent. to exceed it by 150 per cent. without difficulty. If the Government said that this spirit was of great value in their factories for the purpose of aeroplanes he asked them whether they had warned their employees in those factories to be careful how they used this thing; that it was a substance about which scientific opinion had expressed the strongest possible views; that they must not let it touch their hands, nor must they breathe the vapour; they must take the utmost care, because if they did not they might fall upon some disaster. If it was absolutely essential that this spirit should be used by Government employees it might be that the men, properly warned, must run the risk. But for private motor-cars there was no reason whatever to justify the fact of a single man hazarding either his life or his health simply for the purpose of enabling petrol to be used which would drive a car faster than the law permitted it to go. He found in a local paper another scientific man writing a full account of this spirit and of the diseases which followed on its use. He said:—

"In the account of the four deaths by poisoning with tetra-ethyl in the United States which took place Oct. 25th-30th, 1924, it is said——"

The Marquess of SALISBURY (Lord Privy Seal) asked where these deaths occurred was it in America?

Lord BUCKMASTER: In America most undoubtedly. You have not had time to kill people here yet. The writer he was quoting went on:—

"it is said that the victims became raving madmen, much resembling those suffering from delirium tremens. In those cases, which lasted longer, there was constant excitement, with hallucinations. The sufferers imagined themselves beset with foes of every kind about to injure them, while in those who recovered loss of sleep, terrifying dreams, morning sickness, loss of appetite, headache, great weakness."

He did not want to read to their lordships the whole medical catalogue of all the sufferings which these wretched people had to undergo. It was sufficient to say that the result of this poison, if it did affect people, was something that was indisputably grave, that it was almost incapable of remedy, that it was cumulative, and that it was slow in action. Those were the very things that he would have thought they ought to have protected themselves against. He had received a communication written by a woman from New York. He could not say whether it was right or wrong, but what she said was that Dr. Harris, the Commissioner of the Board of Health of New York City, had long since forbidden the sale of this spirit in New York City, although it was allowed in New York State. Switzerland, a country which was pre-eminent throughout the whole of Europe for the high quality of its medical men, had forbidden the use and sale of this spirit throughout the whole country. Did their lordships think that was done out of spite? It had been done because their scientific knowledge informed them that its use was dangerous. He (Lord Buckmaster) had no feeling about tetra-ethyl spirit at all, but he would ask Lord Salisbury to go back into history and see whether it was the operation of industry and commerce that redeemed the factories from the disgrace of child labour, or whether it was not a great-hearted Member of their Lordships' House. Was it the tenderness of conscience of the distilleries that stopped the sale of raw spirits to the infinite degradation and demoralisation of the native races of Africa? The object of all law and of all restrictions was to bring the general standard of conduct of all the people up to the level of those of the highest principle in their class.

Appointment of a Committee.

Viscount GAGE, replying for the Ministry of Health, said that he did not anticipate being able to relieve the gloom which Lord Buckmaster felt on this matter, except that he was able on behalf of his right hon. friend to announce that, in response to the representations of the noble lord, and in conformity with the promise made by Lord Salisbury some time ago, the committee for which the noble lord pressed had been set up as follows:—

The chairman was to be Sir Frederick Wallace, Chairman of the Board of Control; the departmental representatives were: Ministry of Health, Sir George Buchanan; Home Office, Dr. Bridge, Senior Medical Inspector of Factories; Air Ministry, Mr. D. R. Pye, Deputy Director of Scientific Research; the Medical Research Council, Sir Charles Martin, Director of the Lister Institute; the Government Chemist, Sir Robert Robertson; the War Office, Major Galwey, Director of Experiments in the Chemical Warfare Department; and the Department of Scientific and Industrial Research, Dr. C. H. Lander, D.Sc., Director of Fuel Research. The non-official members were Prof. A. C. Chapman, an eminent chemist, Sir William Willcox, and Prof. W. E. Dixon. Mr. S. F. S. Hearder is to be secretary of the Committee and all communications should be addressed to him at the Ministry of Health, Whitehall, London, S.W. 1.

The terms of reference to the committee were:—

"To inquire into the possible dangers to health resulting from the use of motor spirit containing lead tetra-ethyl or similar lead-containing compounds, and to report what precautions, if any, are desirable for the protection of the public or of individuals in connexion with the use or handling of such motor spirit."

It would be seen that the committee was principally an inter-departmental one, but that it had, in addition, a number of independent experts among its members. He understood that the committee was ready to sit immediately, and in conformity with the usual practice it would be left to them to decide whether they would take evidence in public, but he was informed that there was no reason to suppose that the committee would have any objection to the noble lord's suggestion. It was impossible to give any accurate forecast of the date on which the final report would be presented. It must be evident that, having regard to the length of time occupied by the American Commission, the investigations of this committee, if they were to have any value, must be very extensive and prolonged. As to any interim action by the Ministry, it must be evident that the marketing of oil fuel was a competitive business, and obviously it would be a very strong measure for the Government to take if they were to prejudice the products of a particular firm by such an official warning as Lord

Buckmaster suggested unless they had the very strongest reason for doing so. He would point out that when tetra-ethyl spirit was first introduced in America some five years ago it resulted in an agitation there of considerably greater dimensions than the agitation had reached in this country, so much so that the firm which introduced the spirit voluntarily suspended the sale of it until inquiry had been made. There had been three inquiries in the United States into this matter—one by the United States Mines Department in 1923, one conducted by the company itself, and one conducted by the Surgeon-General's Department in Washington, from the report of which Lord Salisbury quoted in the last debate. Those inquiries were very elaborate, and the inquiry by the Surgeon-General's Department in particular entailed experiments not only having regard to the effects of this particular substance on animals, but also on human beings. Reports of an extremely voluminous character were issued to which Lord Buckmaster could have access at the Ministry of Health. Those committees have not found any actual evidence that harm had resulted from the ordinary commercial use of tetra-ethyl petrol. They did recommend—though he thought that he was right in saying that no legislation was introduced—that certain precautions should be adopted both in regard to its manufacture and its distribution in garages. Whether it was due to these precautions, or whether to some other reason he (Lord Gage) thought the following extract from a letter dated March 3rd, and written by the Surgeon-General to the Ministry of Health, was very important as bearing on this matter. The letter said:—

"As a result of this report, the precautions recommended by this Commission [that is the American Commission] for the manufacture of the substance have been carried out and the effect of the use of ethyl spirit on the distributers throughout a large area of this country has been under the immediate observation of the Public Health Service in coöperation with the authorities of the University of Cincinnati and others. I may add that notwithstanding the late publicity given to the investigations and the general use of the substance all over the United States and Canada, no instance of lead poisoning has been reported in the lay or medical press or to any of our Federal or State authorities."

Before condemning the Ministry of Health he (Lord Gage) thought that their lordships should take into consideration the experience of the whole of the Continent of North America where, after a precisely similar agitation conducted both by private individuals and the Press, after prolonged experiments and observations by the most authoritative examiners, no one during the whole of the five years that the spirit had been in use had been able to discover a single case of lead poisoning arising from the use of this substance, although its consumption, he was given to understand, ran into several millions of gallons a year. He was informed, he believed accurately, that the conditions under which this tetra-ethyl was blended with petrol in this country were precisely similar to those prevailing in America. They were under the close supervision of the Home Office, who had satisfied themselves that strict attention was paid to all the precautions found necessary in America, and that those precautions were fully adequate to meet the risk of poisoning. He was further informed that the conditions of distribution in this country were precisely similar to those prevailing in America. That was the case from the point of view of the Government. The committee which had been set up if they found evidence which might controvert in any way the findings of these American committees could, of course, at any time issue an interim report on which the Minister could make immediate application to Parliament for powers. In the Petroleum Bill which was now awaiting a third reading in the House of Commons there was a clause which enabled the Minister to make regulations as to the distribution or manufacture of any class of petroleum spirit which appeared to him to be dangerous or injurious to health, and this Bill would come before their lordships immediately after the Easter recess. He understood that substances containing lead compound equally poisonous in nature were manufactured and retailed subject only to the same restrictions and regulations as prevailed in the manufacture and distribution of tetra-ethyl petrol. He was speaking, of course, of commercial products, and not of chemical compounds. The Minister of Health was not in the least persuaded that until the committee had had time to issue at least an interim report the public would suffer any serious risk.

Viscount HALDANE said that he did not consider the announcement which had been made satisfactory in all respects. It was not enough that the committee should have power to make an interim report if it thought it desirable. He urged that the Government should issue an instruction to the committee to make an interim report on the question whether *prima facie* this substance was of a dangerous character, and whether there ought to be some restriction of its use. It might be a long time before a final pronouncement could be made.

The Danger of Poisoning.

Lord MONTAGU OF BEAULIEU said that there was an affinity between tetra-ethyl and lead glaze. If a person put tetra-ethyl on his hand and let it rest there the chances were that he would be poisoned. Wherever they had lead in suspension in very small quantities there was that danger. There was also danger arising from the fact that the ordinary exhaust from a motor car consisted of carbon-monoxide, and if they added a certain amount of lead in the form of tetra-ethyl it made carbon-monoxide more liable to cause insensibility. He had definite cases, the facts of one of which he held in his hand, of the effects of an exhaust of a car running on the road on the driver and the occupants of the saloon which was being driven. That was a matter which ought to have been inquired into before now. The American inquiries were not very conclusive when read carefully, and, in addition, it should be remembered that the sale of tetra-ethyl was not allowed in New York City, and that it was absolutely barred in the tunnel which ran under the Hudson River. Only a few days ago he had a letter from a gentleman residing at Aldershot in which he said that a son of a friend was suffering from bad lead poisoning as a result of absorbing tetra-ethyl through an abraised knuckle. There was sufficient evidence to make people who used this petrol very careful in doing so. He was also of opinion that the Government had been somewhat dilatory in setting up an inquiry, because it had been well known that there was danger. He made inquiries in France about a month ago, and he found that tetra-ethyl was not sold there.

The Marquess of SALISBURY said that with reference to the terrible instances of the results of the use of tetra-ethyl given by Lord Buckmaster—instances which he did not deny—it should be remembered that they referred to the handling of the poison itself before its combination with the petrol. It was admitted that this poison was a very strong poison. Of course, it was a very dangerous thing to deal with, as indeed there were many other elements in what went to make a commercial commodity which were dangerous. And yet they did not forbid them; what they did was to insist that certain precautions should be followed in the handling of these very dangerous substances. The committee which had been appointed would sit at once, and it was hoped to expedite its proceedings. He did not see what more could be done at this stage.

After further debate Lord Buckmaster's motion was rejected by 36 votes to 21.

HOUSE OF COMMONS.

TUESDAY, MARCH 27TH.

Supervision of Charities.

Sir ALFRED HOPKINSON asked the Home Secretary whether it was intended during the present session to bring in legislation to give effect to the recommendations of the departmental committee on the supervision of charities.—Sir W. JOYNSON-HICKS replied: A Bill for this purpose is in preparation, but I fear that it will not be possible to take it this session.

WEDNESDAY, MARCH 28TH.

Sanitation in Rural Districts.

Sir ROBERT THOMAS asked the Minister of Health whether he was aware that the sanitation of many rural districts was unsatisfactory; that local authorities were seldom able, for financial reasons, to exercise the powers they possessed; that consequently the Public Health Act of 1878 was to this extent a dead letter; and whether he would introduce legislation to modify the Public Health Acts as they affected villages and afford local authorities financial help from the Exchequer.—Sir KINGSLEY WOOD replied: The question raised by the hon. Member is at present, with other questions of local government, engaging the attention of the Royal Commission under the chairmanship of Lord Onslow. My right hon. friend must await the result of their deliberations, though he may say that he could hold out no hope of Exchequer assistance towards purely local obligations of this kind.

Health Conditions in Cornish Mines.

Mr. KELLY asked the Secretary for Mines what reports had been received from his officers regarding the condition of tin mines in Cornwall, especially the effect on the health of the workpeople.—Mr. HERBERT WILLIAMS (Parliamentary Secretary to the Board of Trade) replied: The health conditions of these mines are inspected by one of H.M. Inspectors stationed in Cornwall, and his reports show that generally they are satisfactory, and have improved of recent years.

Small-pox among Vagrants.

Mr. JOHN BAKER asked the Minister of Health how many cases of small-pox had occurred amongst vagrants visiting

casual wards during the past 12 months; when the last case occurred; and whether any measures were still being taken to prevent the spread of infection.—Mr. CHAMBERLAIN replied: I have no definite information as to the number of cases, but small-pox is known to my department to have occurred in some 60 casual wards during the present year. The most recent cases were reported on March 26th. As regards the last part of the question, I have renewed the instruction that, with a view to detecting cases of small-pox, all persons admitted to the casual wards of poor-law institutions shall be medically examined.

THURSDAY, MARCH 29TH.

Small-pox Hospital Accommodation.

Lieut.-Colonel FREMANTLE asked the Minister of Health what number of beds were available for small-pox, respectively, under the Metropolitan Asylums Board, the Surrey County Council, the Uxbridge joint hospital board, and the Willesden urban district council; what number were occupied, and what number are vacant; was he aware that two cases of small-pox occurring in the infirm ward at the Brentford union institution had to be isolated in that institution from March 16th to March 22nd, and another case from March 25th, rather than in a small-pox hospital; and whether he would secure that vacant beds in small-pox hospitals should be available for cases of small-pox from neighbouring areas, subject to proper chargeability of expenses incurred.—Mr. CHAMBERLAIN replied: The numbers of beds available for small-pox under the Metropolitan Asylums Board, the Surrey small-pox hospital committee, the Uxbridge joint hospital board, and the Willesden urban district council are 2123 (approximately), 19, 26, and 25 respectively. Of these beds only six are occupied at the present time. The answer to the third part of the question is in the affirmative. As regards the last part, while I am willing to do what is possible by persuasion, my hon. and gallant friend is no doubt aware that I have no power to require authorities possessing small-pox hospital accommodation to admit patients from other districts, the councils of which have made either no provision or inadequate provision for the purpose.

Boards of Guardians and Vaccination.

Sir COOPER RAWSON asked the Minister of Health whether it was proposed to take any, and if so what, action with regard to the resolutions received from boards of guardians or other local authorities calling for the abolition of Section 1 of the Vaccination Act, 1907, the effect of which would be to make vaccination compulsory; and how many resolutions he had received.—Mr. CHAMBERLAIN replied: This question will be considered in connexion with the report of the Committee on Vaccination presided over by Sir Humphry Rolleston. During the past five years I have received resolutions on this subject from 514 boards of guardians and other local authorities.

Royal Commission on Local Government.

Mr. WELLOCK asked the Minister of Health when the second report of the Royal Commission on Local Government would be ready for presentation.—Sir WILLIAM JOYNSON-HICKS (Home Secretary) replied: The Commission are still engaged hearing evidence, and it is not possible to make any statement as to the date on which the second report will be presented.

Voluntary Hospitals and Motor Accidents.

Mr. LUNN asked the Minister of Health if he was aware that many voluntary hospitals were being seriously affected financially by reason of the additional cases caused by motor accidents they had now to deal with; and whether the Government or the Cave Commission had considered what could be done to assist the hospitals to meet the increased cost made necessary in dealing with these cases.—Mr. CHAMBERLAIN replied: I understand that the question raised by the hon. Member has been considered by the Voluntary Hospitals Commission, and is dealt with in their report which will be issued shortly.

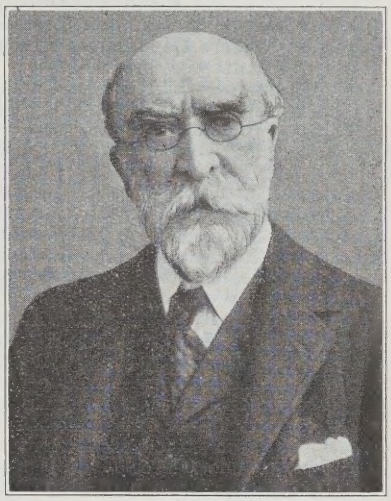
The Foundling Hospital Site.

Mr. ROBERT MORRISON asked the Minister of Health whether he would withhold his sanction from the proposal to erect a large block of flats, 97½ feet high, on the Foundling Hospital estate, in view of the importance of this open space, until the report of the Royal Commission upon Open Spaces had been published.—Mr. CHAMBERLAIN replied: The site of the Foundling Hospital, which is understood to be the site of the proposed flats, is not considered to come within the terms of reference of the Royal Commission on London Squares. The London County Council, under the Town Planning Act, have power to permit the erection of the flats referred to, and if they decide to give the permission, I have no authority to interfere.

Obituary.

GEORGE STEVENSON MIDDLETON, M.D., LL.D., F.R.F.P.S. GLASG.

Dr. G. S. Middleton, who died on March 21st, was a well-known figure in the medical life of Glasgow for a period of nearly 50 years. Born at Aberdeen in 1853, he was educated at the grammar school in that city and graduated as Master of Arts in the University before going south to study medicine at Glasgow. As a student he was recognised by his teachers, as well as by his classfellows, as a man of unusual ability; and from 1881, when he was appointed University assistant to Sir William Gairdner, the Regius Professor of Medicine, he had much to do with the moulding of character and determining the outlook of the students in the Glasgow School of Medicine, most of whom, at one time or another, passed under his instruction. Middleton had a great admiration for his chief, whom he always spoke of as being one of the most eminent physicians of the nineteenth century. Gairdner's teaching—his precept and example—was of the nature of an inspiration to all his students, and on his young assistant it had a very special influence. Of Gairdner's assistants and pupils Middleton was probably the one of all others who most faithfully carried out the Gairdner tradition for thoroughness in clinical investigation, as well as zeal in the study of morbid anatomy. Much of the class work at this time fell to the assistant, and the part that Middleton played in epitomising and preparing students for the final examination in medicine must be gratefully remembered by many hundreds of his former pupils.



DR. G. S. MIDDLETON.

Photograph by T. and R. Annan.

In 1894 Middleton was appointed physician to the Glasgow Royal Infirmary, and a few years later to the Royal Hospital for Sick Children. He now gave up systematic teaching and devoted himself entirely to clinical work. This period of his life was a very happy one, for he was full of enthusiasm for his work and he was on the best of terms with his various assistants and residents, as well as the students in his clinic. Many graduates would attend his ward visits, especially at the week-ends and in vacation time, and those who had this privilege derived great benefit and pleasure from association with their friend and teacher. From the time Middleton got charge of wards he soon acquired a busy consulting practice, and he made a most satisfactory consultant. He would quickly sum up the main points of the case, and he spoke wisely and well to the patients and to the patients' friends. He was invariably considerate of the feelings and interests of the practitioner under whose care the patient might be. He was, indeed, a very sound physician whose opinion was much valued and much in demand. Beyond recording some interesting cases he did not contribute much to medical literature, and his chief legacy to medicine has been the high standard of work which he always set before himself and impressed on all with whom he

came in contact. In thought and conduct likewise he had a very high standard, coupled with a quick appreciation for anything that was worthy in his fellows. A sincere and honest man, he had a warm heart and a genius for friendship, and was himself a staunch and loyal friend.

Dr. Middleton retired from practice two years ago, and on his seventy-third birthday was entertained by a large gathering of fellow-students, colleagues, and assistants.

HENRY LAWRENCE McKISACK, M.D.R.U.I., F.R.C.P. LOND,

DEEP regret is felt in Northern Ireland at the death of Dr. H. L. McKisack, which took place on March 26th after a brief illness. The medical profession in Belfast had no more popular member, and he was widely esteemed both for his personal qualities and his ability as a consultant. Born at Carrickfergus in 1859, Dr. McKisack was the son of the late James McKisack, of Belfast. He was educated at Holywood, Broadstairs, and Queen's College, Belfast, where he graduated with honours in the Royal University in 1887. After holding house appointments at the Royal Victoria Hospital, Belfast, he served for a time as gynæcologist to the Ulster Hospital for Women and Children, and took courses of post-graduate study in Dublin, London, and Birmingham. Appointment to the honorary staff of the Royal Victoria and other hospitals soon followed and Dr. McKisack embarked on successful practice as a consultant in Belfast. He became a Member of the Royal College of Physicians of London in 1904 and was elected to the Fellowship in 1916. A past-president of the Ulster Medical Society, he presided over the Ulster Branch of the British Medical Association in 1914–15, and served for many years as lecturer in clinical medicine in the Queen's University, Belfast, being also an examiner in medicine at Trinity College, Dublin. His teaching became widely known by the publication of two books on diagnosis and case-taking. He managed to read widely in general and scientific literature in spite of a busy life, whose responsibilities were increased during and after the war by appointment to the Ministry of Pensions staff for Ulster and to the Ulster Volunteer Force Hospital. One of Dr. McKisack's sons was killed whilst serving with the Royal Flying Corps, and his wife died last year. He leaves one son.

LANDEL ROSE OSWALD, M.B. GLASG.

THE death is announced of Dr. L. R. Oswald, who was for 21 years physician-superintendent of the Glasgow Royal Mental Hospital at Gartnavel. A Fifeshire man, Dr. Oswald studied medicine at Glasgow University and graduated in 1888, winning the Brunton Memorial Scholarship for the most distinguished medical graduate of his year, and the Foulis Scholarship. After a year spent as assistant house physician to Sir William Gairdner, he was appointed to the staff of the Royal Mental Hospital under Dr. David Yellowlees. Then came a short period spent in travel in the United States and Germany, followed by appointment, in 1895, as superintendent of the Glasgow District Mental Hospital at Garloch. Six years later he was back at Gartnavel as successor to Dr. Yellowlees, and he held the post of superintendent there until 1921, when ill-health made retirement necessary. During the intervening period Dr. Oswald was associated with the University as lecturer on insanity and was instrumental in starting an out-patient department for the treatment of mental and nervous diseases at the Western Infirmary. Interested in the research institute which works in mental hospitals in Western Scotland, he became recognised as a progressive and reliable psychiatrist and served as president of the Section of Mental Diseases of the British Medical Association, and of the West of Scotland Medical Association. His death on March 24th followed a long period of poor health.

FRANCIS BARCLAY WILLMER PHILLIPS, M.D. OXF., B.Sc. LOND., D.P.H.

WE have to record the death on March 23rd of Dr. F. B. W. Phillips, medical officer of health for the borough of Bedford for the last 23 years. A native of Hove, Dr. Phillips was educated at Balliol College, Oxford, and Guy's Hospital, qualifying as M.R.C.S. Eng. in 1883. He gained considerable experience of hospital work as house physician and resident obstetrician at Guy's, as assistant medical officer to the Eastern Small-pox and Fever Hospital, as resident clinical assistant at the East London Hospital for Children, and as clinical assistant at the Evelina Hospital and London Fever Hospital. Forty years ago he went to Bedford as a general practitioner and soon afterwards was appointed physician to the Bedford County Hospital and surgeon to the Bedford Provident Dispensary. In 1905 he became medical officer of health for the borough, and although 71 years of age, was still holding this office at the time of his death. Since the beginning of the year he had been kept hard at work by an outbreak of small-pox at the Bedford Poor-law Institution, and it is believed that his strenuous exertions in connexion with this epidemic were the immediate cause of his death.

Dr. Phillips, who was unmarried, was buried at Hove on March 27th.

RICHARD WILSON MULLOCK, M.D. DUB.

AT the age of 52, Dr. R. W. Mullock died on March 23rd at Southwold, where he had been in practice for many years. Educated at Trinity College, Dublin, he qualified in 1900 and went to South Africa as civil surgeon attached to the Royal West Kent Regiment. Soon afterwards he settled at Southwold, where he was elected to the Town Council in 1905, and held a number of local appointments. He was medical officer to St. Felix School and to the Post Office, and was honorary medical officer and radiographer to the Southwold Cottage Hospital, where his work was held in high esteem. During the late war he worked as chief medical officer of the hospital at Henham Hall and as commandant of the Local Voluntary Aid Detachment. A keen Freemason and sportsman, Dr. Mullock was popular in the district both among laymen and his professional colleagues, and was president-elect of the Suffolk branch of the British Medical Association. He leaves a widow, two sons, and a daughter.

JAMES BUCHANAN YOUNG, M.B., D.Sc., F.R.S. EDIN.

AFTER a short illness, Dr. J. B. Young died on March 17th at the age of 62. By his long association with the teaching of public health at Edinburgh he will be remembered by many generations of students who had the advantage of his instruction. Himself a graduate of the University of Edinburgh, he took his medical degree in 1890 and later proceeded to the B.Sc. and D.Sc. in public health. Soon after completing his medical studies he was appointed to the forensic medicine department, and when six or seven years later this department divided its functions, he became assistant in public health. In 1902 he took up work under Prof. Hunter Stewart at the Usher Institute, and seven years ago was appointed first lecturer in public health, continuing in this office when Colonel P. S. Lelean succeeded to the chair in this subject.

PRINCE OF WALES'S HOSPITAL, TOTTENHAM.—At the festival dinner of this hospital at the Mansion House Sir Berkeley Moynihan said that the institution had distinguished itself by throwing its doors wide open to the general practitioner and had established its fame already as a post-graduate hospital. It was announced that over £33,000 had been obtained towards the £50,000 asked for to pay off the debt and make some provision for recurring annual deficits.

Medical News.

UNIVERSITY OF OXFORD.—At a congregation on March 31st the degree of B.M. was conferred on D. H. Brinton and Olive H. Lister.

UNIVERSITY OF ABERDEEN.—At a graduation ceremony on March 28th the following degrees and diplomas were conferred :—

M.D.—F. Pearce Sturm (awarded highest honours for thesis), T. J. C. MacDonald (awarded commendation for thesis), A. M. Geddes.

M.B., Ch.B.—*F. R. Selbie (with first-class honours), †W. C. Davidson, and †M. G. Gibb (with second-class honours), Isabella M. O. Allan, E. R. Allison, N. J. Barron, W. J. Cumming, E. A. Cunliffe, †G. K. Ferres, H. D. Findlay, K. M. Finlayson, C. A. François, A. H. H. Fraser, E. R. Gauld, Dorothy F. Geershon, J. A. L. Innes, F. J. Lees, D. MacKenzie, F. E. Massie, G. E. Ord, J. B. W. Rowe, J. C. Smith, I. J. A. Stewart, R. Sutherland, G. H. Swapp, R. S. Venters, and P. M. Watt.

D.P.H.—Jean N. Howie, Aileen A. Nicol, E. R. Sorley, and M. Taylor.

* Completed Final Medical Professional Examination with much distinction. † With distinction.

ROYAL COLLEGE OF SURGEONS, EDINBURGH.—At a recent examination, out of 33 candidates entered, the following passed the Final Dental Examination and were granted the Diploma of L.D.S. :—

J. G. Stewart, H. G. Simon, J. M. Macdonald, R. M. Cameron, R. H. White, H. E. Gersohn, F. P. MacGillivray, R. McA. Blair, W. G. Hetherington, J. H. Rossouw, D. Silverston.

The following candidates passed in the undermentioned subjects :—

Pathology.—J. R. Rennie, K. MacGillivray, Elizabeth A. Wilson, D. A. H. Brown, A. C. J. Alexander, A. R. Hardy, F. T. C. Reakes, A. D. Dickson.

Medicine.—Dorothy Williams, H. G. Somerville, J. R. Rennie, C. V. Armitage, K. MacGillivray, Elizabeth A. Wilson, N. J. W. Smith, C. W. Collee, R. T. Amour, A. R. Hardy.

Surgery.—Dorothy Williams, H. G. Somerville, J. R. Rennie, C. V. Armitage, N. J. W. Smith, C. W. Collee, R. T. Amour, F. T. C. Reakes.

Dental Subjects.—A. C. J. Alexander, A. R. Hardy, J. F. Miller.

UNIVERSITY COLLEGE HOSPITAL.—The annual general meeting of the corporation of University College Hospital was held in the board room on March 29th, when Sir Herbert Samuelson, the chairman and treasurer of the hospital, presided. On the motion of the Chairman, Prince George was elected president of the hospital in succession to the Duke of Bedford, who has retired, and the officers for the year were afterwards chosen, Mr. A. G. Gumpert being elected vice-treasurer in view of the increasing financial responsibilities of the treasurer in consequence of hospital extensions. In moving the adoption of the annual reports and audited accounts for the year 1927, the Chairman referred to the loss which the hospital had sustained by the death of the chairman and treasurer, Sir Ernest Hatch, and of the vice-chairman, Lord Oranmore and Browne. Reviewing the progress of the hospital, Sir Herbert Samuelson said the principal event of the year was the opening of the new Royal Ear Hospital in Huntley-street, now incorporated with themselves and due principally to the munificence of Lieut.-Commander Geoffrey Duveen ; this hospital had already proved a valuable help to treatment and research, while eight single-bedded wards had been provided for patients of moderate means. The expenditure on the Royal Ear Hospital had been double that incurred for the old building—namely, about £6000 a year—and £3000 a year was required to meet additional expenditure. Progress had been made in the reconstruction work of University College Hospital, and the new south-west wing, which was opened in October last, contained 95 additional beds. There were new massage rooms, Finsen light and orthopædic departments, and three new operation theatres. A special feature of the hospital was the children's clinic which had been instituted under Dr. Wilfred Pearson. Through this department children were treated and watched from infancy to school age. The work in the genito-urinary department had been extended and a new clinic for mental defectives, under the charge of Dr. A. F. Tredgold, would give facilities to students which had not hitherto been available. The institution had accumulated a debt of £30,000, towards which £2900 had been received or promised, and although the appeal had not yet been really launched he could say that preparations had been made for a magnificent ball which he hoped would add considerably to the funds, while a dinner, it was hoped, would be held at the Mansion House at the end of the year. At the conclusion of the meeting Sir Courtauld Thomson revealed the name of a previously anonymous donor, who had promised £5000 to the hospital on condition that £2500 was subscribed by others. This, he said, was Sir Herbert Samuelson, who had agreed that his name should be known, hoping that the fact that one so closely associated with the institution was contributing would give confidence to other donors.

UNIVERSITY OF ST. ANDREWS.—The Senate has resolved to confer the degree of Doctor of Laws on Dr. E. P. Cathcart, F.R.S., Professor of Physiological Chemistry in the University of Glasgow, and Prof. William Darroch, Dean of the Medical School, Columbia University, New York.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting will be held on Friday, April 13th, at 8.45 P.M., at the Miller General Hospital, Greenwich. Mr. R. Ogier Ward will give an address on Some Difficulties in the Diagnosis and Treatment of Urinary Diseases.

NATIONAL HOSPITAL, QUEEN-SQUARE.—A post-graduate course on Diseases of the Nervous System will be held at this hospital from May 7th to June 29th. Particulars may be had from the Secretary of the Medical School, National Hospital, Queen-square, London, W.C.1.

NAVAL MEDICAL COMPASSIONATE FUND.—A meeting of the subscribers of the above fund will be held on April 26th, at 11.30 A.M., at the Medical Department of the Navy, Queen Anne's Chambers, Tothill-street, London, S.W.1, to elect six directors of the fund.

ROYAL FREE HOSPITAL.—In aid of the Centenary Appeal, the medical staff and students of the hospital are organising a ball to take place on May 1st from 9.30 P.M. to 2 A.M., at the B.M.A. House, Tavistock-square. Tickets may be had from the hospital or from the hon. secretary, May Day Ball, 24, Mecklenburg-square, London, W.C. 1.

Dr. C. M. Rolson (Chief Medical Officer) has been appointed an official member of the Legislative Council of the Presidency of Dominica ; Dr. Kenrick Stanton Wise (Surgeon-General), an official member of the Legislative Council of Trinidad and Tobago ; and Dr. A. H. McShine, an unofficial member of that Council.

LONDON CLINIC FOR RHEUMATISM.—On Sunday last Sir Thomas Horder broadcast an appeal on behalf of the clinic which the British Red Cross Society is hoping to erect near Regent's Park (see THE LANCET, March 10th, p. 505). Donations amounting to more than £21,000 have been received towards the £40,000 required for this purpose. They include contributions from the King, the Queen, and other members of the Royal Family.

EASTBOURNE ROYAL EYE HOSPITAL.—In April, 1924, when new wards and operating theatre were opened, it was thought that this hospital was completed, but the work has so much increased that the governors report that it has become necessary to purchase an adjoining house in Cavendish-place. For this extension they are appealing for £2500.

MEMORIAL TO DR. W. J. FRANCE.—The Lord Mayor of Liverpool recently unveiled a tablet over a bed in the Royal Infirmary of Liverpool, which has been endowed for auto-laryngeal work by the late William James France, F.R.C.S. Edin., hon. surgeon to the Ear and Eye Infirmary, Liverpool.

CANCER CAMPAIGN IN IRELAND.—The National Cancer Campaign is continuing its activity in holding public meetings in provincial centres. On March 30th a meeting was held in the Town Hall, Waterford, under the presidency of the Mayor of Waterford. Addresses dealing with the work of the campaign were given by Sir William Taylor and Dr. Robert J. Rowlette, of Dublin, by the Very Rev. the Dean of Waterford, and by Dr. M. P. P. Higgins, of Waterford. In his address Sir William Taylor spoke of the increasing mortality from cancer, and described the early signs of the various forms of the disease. Dr. Rowlette spoke of the special need in Ireland for provision for research on health matters, and of the problems that await solution in regard to cancer. Steps were taken at the meeting to form a local committee.

SWISS RED CROSS OFFICIALS.—The death is announced of Mr. Gustave Ador, President of the International Committee of the Red Cross, and of Dr. Karl Bohny, chief medical officer of the Swiss Red Cross Society. Mr. Ador, who was 85 years of age, was largely responsible for founding the Prisoners of War agency at Geneva, which centralised the search for missing civilians and soldiers in the theatres of war. He was a Swiss delegate to the Assembly of the League of Nations until 1924 and was elected honorary President of the Assembly in 1921. Dr. Bohny, who has died at the age of 72, was for many years professor of medicine in the University of Basle. During the war he was in charge of the exchange of wounded between Germany and the Allies and for the internment of combatants in Switzerland. Since 1919 he had been President of the Swiss Red Cross.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

FRIDAY, April 13th.—4 P.M., WAR. Annual General Meeting: Election of officers and council. 4.30 P.M., WAR, OTOLOGY. Special discussion on Effects of Middle-ear Disease on Efficiency in Civil and Military Life. Openers: Wing-Comdr. D. Ranken, R.A.F. (War) and Mr. Sydney Scott (Otology); time allowance for speaking, 15 minutes each. Lieut.-Colonel T. B. Layton and Mr. T. Ritchie Rodger (Otology); and Major Hare, R.A.M.C., and Surg-Comdr. Maxwell, R.N. (War); time allowance for speaking, 10 minutes each. Subsequent speakers will be limited to 5 minutes each.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith.

MONDAY, April 9th.—10 A.M., Dr. Dowling: Skin Department. 2 P.M., Dr. Trevor Davies: Gynæcological Department. 2 P.M., Dr. Ironside: Medical Out-patients.

TUESDAY.—10 A.M., Medical Registrar: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose, and Ear Department. 2 P.M., Mr. Addison: Operations.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. Simmonds: Surgical Out-patients.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Department.

SATURDAY.—9 A.M., Mr. Vlasto: Operations on Throat, Nose, and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily, 10 A.M. to 5 P.M., In-patients, Out-patients, Operations, Special Departments, Anæsthetic and Operative Surgery Classes.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 13th.—4 P.M., Mr. Nicol Rankin: Examination of Cases Complaining of Discharge from the Nose.

Appointments.

MONTFORD, T. M., M.B., Ch.B. Glasg., has been appointed Resident Medical Officer, Kettering General Hospital.

THIERENS, V. T., M.B., Ch.B. Liverp., D.P.H., Medical Officer of Health for Blackburn.

King's College Hospital: LIVINGSTONE, J. L., M.D. Lond., M.R.C.P. Lond., Junior Physician; SHELDON, W. P. H., M.D. Lond., M.R.C.P. Lond., Junior Physician for Diseases of Children; HUNTER, J. B., M.Chir. Camb., F.R.C.S. Eng., and EDWARDS, H. C., M.B., B.S. Lond., F.R.C.S. Eng., Junior Surgeons; MOORBY, A. L., M.R.C.S., L.R.C.P. Lond., Junior Anæsthetist; NEWMAN, C. E., M.D. Camb., M.R.C.P. Lond., Senior Medical Registrar; COVE-SMITH, R., M.B., B.Chir. Camb., M.R.C.P. Lond., and DAGGETT, W. I., M.B., B.Chir. Camb., F.R.C.S. Eng., Registrars; NEWMAN, J. L., M.R.C.S., L.R.C.P. Lond., COGSWELL, A. P., M.R.C.S., L.R.C.P. Lond., CUMINGS, J. N., M.R.C.S., L.R.C.P. Lond., BATTEN, G., B.M., B.Ch. Oxf., WHIDBORNE, E., M.R.C.S., L.R.C.P. Lond., SAPWELL, J. I., M.R.C.S., L.R.C.P. Lond., CHILCOTT, J. C. K., B.M., B.Ch. Oxf., HALL, V. F., M.R.C.S., L.R.C.P. Lond., RUTHERFORD, R., M.R.C.S., L.R.C.P. Lond., SHEPPERD, N. L., M.R.C.S., L.R.C.P. Lond.; MACMYN, D. J., M.R.C.S., L.R.C.P. Lond., SCRIVEN, W. H., M.R.C.S., L.R.C.P. Lond., HUMPHREYS-OWEY, I. R., M.R.C.S., L.R.C.P. Lond., GROSS, G. J., M.R.C.S., L.R.C.P. Lond., and FERRABY, G. S., M.R.C.S., L.R.C.P. Lond., Resident Medical Officers; LIMMEX, E. G., M.R.C.S., L.R.C.P. Lond., House Surgeon in the Ophthalmic Dept.; WALKER, T. DE L., L.S.A., Junior House Anæsthetist; MAY, K. S., M.R.C.S., L.R.C.P. Lond., House Surgeon; Aural and Throat Depts.; GILES, C. P., M.R.C.S., L.R.C.P. Lond., LISTER, C. H., B.M., B.Ch., and SHACKLE, M. P., M.R.C.S., L.R.C.P. Lond., Assistant Casualty Officers; and ROBERTSON, W. I., L.D.S., WYBORN, L. A., L.D.S., and MOORE, A. S., L.D.S., House Surgeons in the Dental Dept.

Vacancies.

For further information refer to the advertisement columns.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Bath, Somerset and Wilts Central Children's Orthopædic Hospital. Asst. Res. M.O. At rate of £120.

Brit Memorial Fellowships for Medical Research, 35, Clarges-street, W.—Junior Fellows. £400.

Birmingham, Highbury and Uffculme Hospitals.—Jun. Res. M.O. £300.

Bolingbroke Hospital, Wandsworth Common, S.W.—Out-patients' Officer to Ophth. Dept. £35.

Bradford Royal Infirmary.—Two H.S.'s and H.P. Each £150.

Bury and District Joint Hospital Board.—Res. Asst. to Med. Supt. £400.

Calcutta School of Tropical Medicine.—Research Worker. Rs. 1250 per mensen.

Cambridge, Addenbrooke's Hospital.—Res. Anæsthetist. At rate of £180.

Carlisle Non-Provident Dispensary.—Res. M.O. £250.

Chesterfield and North Derbyshire Royal Hospital.—Jun. H.S. and Cas. H.S. Each at rate of £100.

Connaught Hospital for Walthamstow, Wansted and Leyton.—Jun. Res. H.S. At rate of £100.

Derbyshire, Royal Infirmary, Derby.—H.S., Asst. H.S., and Cas. O. Each £150.

Dreadnought Hospital, Greenwich.—Anæsthetist. 50 guineas. Also Surgeon in charge of Out-patients.

Gravesend and North Kent Hospital.—Res. M.O. and H.S. At rate of £250 and £150 respectively.

Grocers' Company.—Research Scholarship. £300.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Guildford Union Institution, Warren-road.—Res. M.O. £500.

Halifax Royal Infirmary.—Third H.S. At rate of £100.

Hampstead General and North West London Hospital, Haverstock Hill, N.W.—H.S. and H.P. Also Cas. M.O. Each at rate of £100.

Infants Hospital, Vincent-square, Westminster.—Med. Reg. £120.

Laboratories of Pathology and Public Health, 6, Harley-street, W.—Asst. Pathologist. £500.

Liverpool Eye and Ear Infirmary.—Third Hon. Anæsthetist.

London Hospital, E.—First Asst. and Reg. to one of the five Surg. Firms. £300.

Lucknow University.—Professor of Anatomy. Rs.1450 per mensem.

Manchester Royal Infirmary.—Dickinson Research Travelling Scholarship in Medicine. £300. Also Dickinson Surgery Scholarship. £75.

Metropolitan Hospital, Kingsland-road, E.—Sen. H.P. and Sen. H.S., Jun. H.P. and Jun. H.S. Also two Cas. O's. Each at rate of £100.

Ministry of Health, Whitehall, S.W.—Deputy Regional M.O. £800.

Nottingham General Dispensary.—Res. Surg. £250.

Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £120.

Plymouth, South Devon and East Cornwall Hospital.—Cas. H.S. At rate of £50.

Portsmouth, St. Mary's Infirmary, &c.—First Asst. Res. M.O. £350.

Preston, Lancs, County Mental Hospital, Whittingham.—Sixth Asst. M.O. £350.

Rochdale, Birch Hill Hospital and Institution, Dearnley.—Asst. Res. M.O. £250.

Royal Chest Hospital, City-road, E.C.—Res. M.O. At rate of £150.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.

St. Mary's Hospital for Women and Children, Plaistow, E.—Asst. Res. M.O. At rate of £130.

Sheffield, Children's Hospital.—Jun. H.S. £100.

Sheffield Royal Infirmary.—Hon. Radiologist.

Torquay, Torbay Hospital.—Res. M.O. £200.

Walsall County Borough.—Clin. Tuberculosis O., &c. £750.

Walsall General Hospital.—H.S. At rate of £125.

West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Registrar. £200.

Births, Marriages, and Deaths.

BIRTHS.

EDWARDS.—On March 26th, at Sutherland-avenue, the wife of Harold Edwards, F.R.C.S., of a son.

HOSFORD.—On March 30th, at Hornsey Lane-gardens, Highgate, N., the wife of Reginald W. P. Hosford, F.R.C.S., of a son.

MELVILLE.—On March 27th, at Lancaster-road, N.W., the wife of William Spence Melville, M.B., Ch.B., of Hornsey rise, N., of a daughter.

SUTHERLAND.—On April 1st, at a nursing home, the wife of Halliday Sutherland, M.D., New Cavendish-street, W., of a son.

MARRIAGES.

BOOG WATSON—SVOBODOVA.—On March 24th, at the Town Hall, Prague, and afterwards at the Church of the Bohemian Brethren, Vinohrady, Prague, William Nairn Boog Watson, M.B., Ch.B., Tor-na-Dee, Murtle, Aberdeenshire, to Vera Marie, only daughter of Dr. and Mrs. Jos. Svobodova, Kladska, Prague, Czechoslavakia.

MCCALLUM—LACAILLE.—On March 31st, at St. Columba's (Church of Scotland), Pont-street, Alexander Grigor McCallum, M.B., Ch.B., to Marion Bowie, elder daughter of the late Fernand Lacaille and Mrs. Lacaille, of Hillhead, Glasgow.

DEATHS.

BRADSHAW.—On March 30th, at "Sherbrook," Bournemouth, William Lucknow Bradshaw, L.R.C.P., D.P.H., in his 69th year.

ELMES.—On March 25th, at Cannes, of pneumonia, Major C. H. Elmes, C.B.E., V.D., M.B., Ch.B.

MCKISACK.—On March 26th, suddenly, Henry Lawrence McKisack, M.D., F.R.C.P., of University-road, Belfast.

POPE.—On March 30th, at The Garth, Hereford, H. B. Pope, M.D., in his 69th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

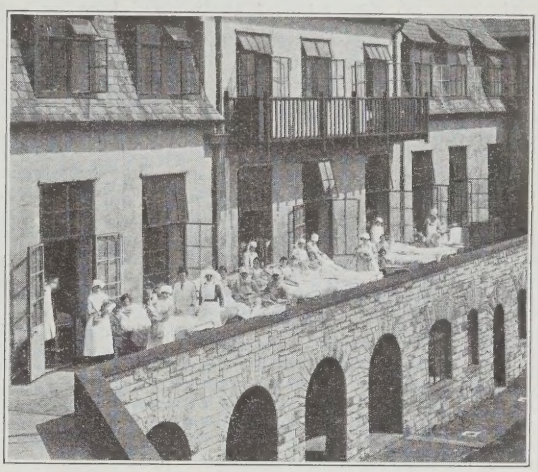
A SCOTTISH MATERNITY HOSPITAL.

Dr. Elsie Inglis, who became famous throughout the world for her work in Serbia with the Scottish Women's Hospitals during the late war, is commemorated in Edinburgh by the maternity hospital which bears her name. Built on a beautiful site commanding a view of King's Park, behind Holyrood, it has now been in use for two and a half years. The work done there is a direct continuation of what Dr. Inglis did in Edinburgh long before the war, and from the latest annual report, which has just been issued, it is clear that the services of the institution are increasingly valuable to the city and appreciated by the citizens. Last summer it became necessary to open all the available wards, and to avoid overcrowding the booking of patients had to be curtailed. A good effect of this, it may be noted, has been to bring the patients to the ante-natal clinics at an earlier stage in their pregnancy.

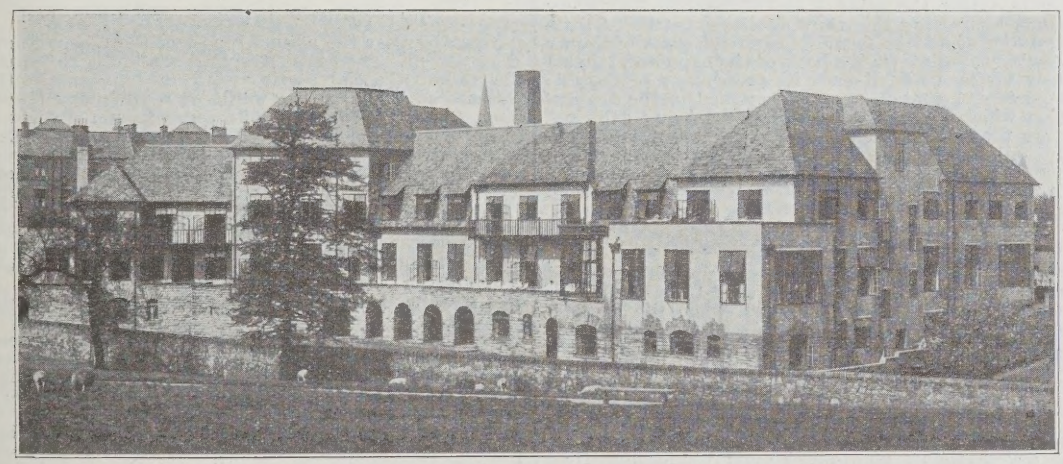
The photographs (by F. C. Inglis, Edinburgh) which we reproduce show some of the attractive features of the building, whose architect was Mr. H. O. Tarbolton. It was laid out in such a way as to make the greatest possible use of a sloping site of unequal boundaries, the longest side being that towards the King's Park. Three main corridors meet in an octagonal centre—one leading into hospital, a second into administration, a third into service and kitchens. The wards, which contain four, three, or two beds each, open on to a wide stone terrace—verandah on the park side, on which beds can be rolled out with ease. The usual offices, district room, receiving room, serving kitchen, baths and lavatories, drying room, side room, and sterilising rooms open to the back. The delivery wing, which is cut off from the wards by special corridor, communicates with the inner sterilising room and theatre nurses' accommodation, and consists of an ante-room of two beds, in the quietest corner of the hospital, a theatre, doctors' scrubbing room, smaller delivery room, and a dismissal room with a separate patients' entrance, where every patient is seen by a member of the visiting staff before leaving the hospital.

At the south-east corner of the building, with sunlight on three sides, are the nurseries, communicating with a part of the verandah enclosed in glass; one is fitted with a glass service table, always warm from the steam-pipe underneath; another contains an enclosure for premature infants as well as bench and basket accommodation for 30 infants. On the first floor is a special self-contained ward for nine beds, with treatment room, sterilising room, and isolation room. Small wards run along the park front as on the floor below, a flat roof doing duty as a verandah; there are isolation wards on both flats. The administration corridor leads on the ground floor to staff dining room and sitting room, board room, staff and secretary's offices, sisters' accommodation, and linen room; above are bedrooms for nurses, and on the second floor accommodation for ten resident doctors. The service corridor leads to kitchen, larders, service hall, and pantry below, and to bedrooms for men above. On a basement flat, but well above ground, are an engineer's house, with separate entrance, drug room and dispensary, pathological room, ward for waiting patients with dining room and pantry attached, ward matron's accommodation, and at the back hand laundry and wash-house, with large drying room. Twin Cornish boilers supply high-pressure steam to the kitchen for cooking, to the delivery block, sterilising rooms and nurseries, reduced steam for heating over the entire building, and an ample domestic hot water-supply.

Since the hospital was opened in August, 1925, the pressure on the beds has increased so rapidly that a nurses' home is under construction, which will contain 36 bedrooms, a recreation room, and a separate flat for chauffeuse. An adjacent bungalow has been acquired which will add ten beds for antenatal use and special isolation. A double-steel bungalow (Atholl type), with playground and sandpit gives satisfactory out-patient accommodation at the hospital gates. With the completion of the nurses' block and adaptation of the bungalow, the hospital will provide 70 beds, with staffs for out-patient service and district work, as well as full in-patient equipment.



A sunny balcony.



General view of the Elsie Inglis Memorial Hospital.

The staff consists of four visiting surgeons and physicians, four resident doctors, a pathologist and a medical registrar; and the nursing staff of the matron, six sisters, two staff nurses, and 20 pupil midwives (most of these being fully trained nurses).

The Elsie Inglis Memorial Hospital is the outcome of 20 years' devoted work by women doctors among wives and mothers living in crowded slum and tenement areas in a large city. The needs of the women close at hand have been keenly realised. The board of management feel that a walk along the terrace-verandah after working hours, when husbands come in to see their wives and babies without restriction, has carried the conviction to many a visitor that the social side of maternity work, with freedom from anxiety, rest in beautiful surroundings, an atmosphere of happiness, is second only to surgical efficiency and thoroughness in promoting the welfare of mother and infant.

NEW PREPARATIONS.

Radiostoleum.—We have received from British Drug Houses, Ltd., 16-30, Graham-street, London, N., a preparation, Radiostoleum, which is described as a highly active mixture of a solution of radiostol (containing vitamin D) and a concentrate of vitamin A in a tasteless vegetable oil, the latter being made in their chemical works from a new source of this vitamin. We recommended radiostol in a recent issue of THE LANCET (Feb. 25th, 1928) in terms suggesting its utility in cases of vitamin D deficiency, and the new preparation proposes to combine therewith a preparation containing vitamin A for its growth and resistance-promoting properties. The preparation might well be tried where cod-liver oil has failed to produce the desired effects. Radiostoleum is put up in boxes containing 50 capsules, the dose being 1 to 2 capsules daily, and in solution, the bottles containing one half a fluid ounce, while the dose ranges from 3 to 6 minims daily. The recommended doses show the concentrated nature of the preparation.

Caprokol.—This preparation also is put on the market by British Drug Houses, Ltd. Clinical reports published on the introduction of hexyl resorcinol indicated certain valuable properties possessed by the drug, and a caprokol antiseptic solution has now been prepared by the British Drug Houses for use in the disinfection of the skin and mucous membranes in cases of abrasion or wound. It can be employed undiluted or diluted with water in varying proportions, when a useful disinfectant is formed for application in nose and throat and in dentistry. Actually caprokol antiseptic solution is a 1 in 1000 solution of caprokol in water and glycerine, 30 parts glycerine to 70 water, possessing a low surface tension and retaining its disinfecting powers under adverse circumstances. It is issued in 3 oz. and 12 oz. bottles with directions for use.

Dimol Catarrh Snuff.—The claims made for Dimol as an intestinal disinfectant, which are supported by the clinical experience of a good many specialists, are well known. The chemical constitution of Dimol is $C_6H_2(CH_3)_2(OCH_3)OH$, and tests have confirmed freedom from toxicity. At the Dimol Laboratories (40, Ludgate-hill, London) there has now been prepared an insufflation powder designed more especially to prevent and remedy nasal catarrh; the literature on the subject will be supplied to any practitioner who applies to the laboratories, while the distributing agents are Messrs. Sangers, 258, Euston-road, London. It is recommended that the snuff should be taken every hour during the acute stage of catarrh, and every two or three hours when the symptoms have abated. A little of the powder should be tumbled from the glass container in which it is supplied on the back of the hand and inhaled vigorously up each nostril until its presence is perceptible to the palate. A container is also supplied to the medical profession which ensures the correct dose being delivered and waste prevented. Relief of the distressing nasal congestion is followed by a decrease in the headache which often accompanies nasal catarrh, and many victims of a tiresome malady may be glad to learn of the preparation through their doctors.

THE TWO-SHIFT SYSTEM.

THE two-shift system of employment was much advocated nine or ten years ago, particularly by Lord Leverhulme, but continued trade depression since 1920, when the employment of protected persons on this system was legalised, has discouraged many employers from introducing it. Nevertheless, it has been tried, and a study has been made of the results. Under this system two shifts of not more than eight hours each may be worked between 6 A.M. and 10 P.M., from Monday to Friday, and from 6 A.M. to 2 P.M. on Saturday. Thus machinery can be kept running for 88 hours a week, though no worker is employed for more than 48 hours. A report now issued [1] contrasts output, lost time, and labour turnover of the same workers when employed as ordinary day-workers and on the shift system. So far as the operatives are concerned, no definite advantage with regard to sickness experienced could be ascribed to either system. In practice the shift-workers were employed for fewer hours than the day-workers, but their hourly output was rather greater and their voluntary rest-pauses were fewer; the final result was 4 per cent. less output per worker. Labour turnover was rather greater on the shift-system, but was far highest when the two systems were interchanged. Once the shift-system was steadily going, habit caused it to be preferred to the day-system, whilst the opposite held good where the day-system was well established. The human factor, indeed, does not seem to be affected for weal or woe by the shift-system. Hence, should trade ever boom again, attention may be drawn to the observation that "an employer who changed from ordinary day-work, with a 48-hour working week, to shift-work, with a total working week of 82 hours, might have expected an increase of output *per machine* of rather over 92 per cent." Such an employer would have 92 per cent. more output over which to distribute his overhead expenses.

A VIRUS IN PNEUMONIC LUNGS.

THE frequent association of labial herpes with pneumonia has long been recognised, and it has been known for some time that labial herpes is caused by a virus which produces an inflammation of the cornea in rabbits, afterwards spreading to the brain and causing an encephalitis; the rabbit reaction is indeed our only means of recognising the virus. Using this test, Dr. J. R. Perdrau (*Jour. Path. Bact.*, 1928, xxxi., 9) searched for the herpetic virus in human lungs; he failed to find it in 50 cases, 26 of which were frankly pneumonic. But in 40 lungs there was some agent present which produced a keratitis in rabbits, independently of any bacteria and transmissible in series; it differed from the herpetic virus in never causing encephalitis, and cross-immunity experiments showed no evidence of any relationship. When the attack induced by rubbing an emulsion of lung on to the scarified cornea subsides, the cornea is more sensitive to a second and third application. The meaning of this new virus is quite obscure; it was found in a variety of pulmonary lesions ranging from simple congestion to lobar pneumonia and was most abundant during a time when pneumonia was epidemic; the data are not sufficient to judge how far it occurs in normal or semi-normal lungs. The discovery of these invisible living agents, which cannot be cultivated, seems to depend mostly on finding some characteristic reaction which will reveal their activities; how much of what goes on in the world is due to them we have at present no idea, but they become more and more important.

THE KEM-DENT STERILE TOOTHBRUSH.

THIS is a tubular glass container at the bottom of which is a cotton-wool pad impregnated with a germicide, its object being to keep the toothbrush sterile. The other end of the tube is closed with a rubber stopper to which the handle of the brush is fixed, but from which it is detachable. By this means the brush can always be kept in a sterilised atmosphere. Enamelled holders to suspend the appliance to the wall are supplied. The makers are the Lavoden Company, Ltd., Denmark-road, West Ealing, London, W.13.

THE CICELY NORTHCOTE TRUST.

YEAR by year the annual report of the Cicely Northcote Trust of St. Thomas's Hospital continues to emphasise the value of social service work in connexion with the patients admitted to the wards of a voluntary hospital—work which has features quite separate and distinct from those characterising out-patient departments. In the eighteenth report just received three main features stand out—the after-care work done for the neurotic and mentally unstable, the after-care of cancer patients, and the Northcote Trust Hostel. With regard to the neurotics, the report points out that one of the outstanding difficulties in helping a patient to re-establish himself in the environment of the world outside a sheltered hospital life is the impossibility of obtaining consecutive and detailed information as to past treatment and to the causes which led up to the sudden admission to institutions. It is suggested that some machinery is necessary for "passing on" histories from one treatment centre to another. The after-care of the cancer patient has a very different aspect from that of the case work for the neurotic. The help needed to make the "bit of savings" last to the end which will inevitably come, the necessity for befriending the unmarried middle-aged women patients with no relations or friends, the provision for the young mother with malignant disease and a family of little ones, these are some of the problems with which the social service department is in daily contact. The Northcote Trust Hostel which ministers to the needs of women and girls from the venereal disease department shows a record of good work amongst many different types of patient admitted. A classification of patients according to mental equipment reveals the fact that 16 were regarded as of normal intelligence out of 40 cases admitted between 1924 and 1925, the remainder showing deficiency or defect of one type or another.

A perusal of this report with its record of manifold activities makes us wonder how any large hospital, special or general, can possibly carry on without a social service department.

Mr. W. H. Martindale, manufacturing chemist, after a tenancy of 54 years at No. 10, New Cavendish-street, London, W., has now rebuilt and opened his pharmacy under modern conditions at No. 12 in the same street, with a wholesale entrance at 33, Hallam-street.

Goulstonian Lectures

ON

SOME PROBLEMS OF NEPHRITIS.

The Third Goulstonian Lecture in 1928 delivered before the Royal College of Physicians of London on March 20th

BY T. IZOD BENNETT, M.D. LOND.,

FELLOW OF THE COLLEGE; PHYSICIAN TO OUT-PATIENTS, MIDDLESEX HOSPITAL, AND TO THE ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.

LECTURE III.*—THE PROBLEM OF BLOOD PRESSURE IN NEPHRITIS.

IN my first lecture I described a case in which the patient died of uræmia following progressive destruction of both kidneys by cystic disease. This case was selected in order, first, that the problem of uræmia might be studied in a case of non-inflammatory destruction of the renal substance, and secondly, because neither œdema nor elevation of the blood pressure was a marked feature of the case. In other words, the case illustrated the important fact that uræmia is not necessarily associated either with renal inflammation, or with so-called "renal" œdema, or with hyperpiesia.

In my second lecture I endeavoured to summarise the evidence by which I think one is driven to the conclusion that œdema occurring in cases of renal disease points to tissues other than the kidneys being affected, whilst there is no evidence to prove that such œdema is the result of the renal lesion.

To-day I approach the subject of high blood pressure, and am at once aware that the problems here are, for the lecturer, even more difficult than those already discussed. For in the case of uræmia and œdema we are confronted with masses of complex data the sifting of which is a task of great complexity, although certain conclusions emerge after close analysis. When considering high blood pressure and its relation to renal disease, on the other hand, one is often confronted with an absence of essential data which makes it impossible to draw conclusions at all.

The patient whose story I discussed in my first lecture, and the man I showed in my second lecture, illustrate the frequency with which hyperpiesis is absent in cases of renal disease. We can perhaps best approach the subject by first inquiring into the groups in whom hyperpiesis is most marked. We at once find that there are three main groups:

(A) Those which constitute what has too often been called "chronic interstitial nephritis," or "granular kidney."

(B) The group which embraces the renal complications of pregnancy, including eclampsia.

(C) The acute glomerulo-nephritis which is seen as a complication of scarlatina and some other infectious diseases.

It will be well to examine these groups in greater detail.

(A) "CHRONIC INTERSTITIAL NEPHRITIS"; ESSENTIAL HYPERTENSION.

Of all cases of renal disease those in this group probably exhibit high blood pressure most prominently. They were well recognised by Bright, who in his Goulstonian lectures spoke as follows:—

"In April, 1830, Dr. George Burrows brought me a kidney in a most confirmed state of granulation, so completely pervaded with deposit as to have lost all the structure of the cortical portion, and to have put on a marked scabrous wall externally. This was taken from a patient who had been in St. Bartholomew's Hospital for a fortnight only with confirmed anasarca, and in addition to the disease of the kidney, the heart was greatly enlarged and otherwise diseased. In this case . . . the urine had shown no tendency to coagulate by heat."

He goes on to quote a still more interesting case brought to his observation by Dr. Watson of the Middlesex Hospital—

"the kidneys showed the typical organic change found in anasarcous patients which is so often accompanied by the secretion of albuminous urine, but this state of the urine did not exist during the time he was under Dr. Watson's observation, and the action of the kidney was so far annihilated that even by gin and stimulating diuretics only a scanty secretion was obtained,"

and he goes on to record the important fact that the heart was much enlarged without any sufficient cause being found. Elsewhere in the same lectures Bright several times remarked on this mysterious association of cardiac hypertrophy and sclerotic kidneys and on the irregularity of albuminuria in such cases.

It is hardly necessary for me to mention that these cases were the subject of the classical studies of Gull and Sutton, who under the name of arterio-capillary fibrosis described the generalised change in the small vessels which is now usually considered the primary cause of the renal changes.

To another physician at Guy's Hospital, Dr. F. A. Mahommed, we owe the continuation of this work and almost the earliest observations on the blood pressure in such cases. He clearly paved the way to the work of Sir Clifford Allbutt and others, who have shown convincingly that in an enormous number of cases of contracted kidney there is evidence of high blood pressure for many years before any renal lesion makes itself manifest. The work of these observers has been well described in a recent article by Ryle.

"Hyperpiesia," "essential hypertension," and "arteriolosclerosis" are synonyms used in the description of this condition, which formed the subject of one of the Goulstonian lectures delivered by Dr. Geoffrey Evans five years ago. Its ætiology remains obscure; it is probable that the high blood pressure is at first the result of a widely distributed spasm of the arterioles, and that the anatomical change which Evans describes as "diffuse hyperplastic sclerosis" is a subsequent event. Moreover, the physiological researches of Anrep and Starling, and the pathological investigations of Bordley and Baker produce evidence that the failing blood-supply to the medulla oblongata is of primary importance in the genesis of these vaso-motor responses which establish the condition of prolonged hypertension.

Whatever will in the future be established as the explanation of this disease, the present evidence seems to be against the probability that the renal changes are either of primary importance or of invariable occurrence. Fishberg in an investigation of 72 of these cases found advanced renal disease present in only five at autopsy, and his conclusion that the anatomical changes of the kidney are not compatible with the theory that hypertension is primarily due to a disorder of the renal function is one which finds increasing acceptance at the present day.

We must, I think, recognise that there are at least three stages in the development of this disease if we include only those cases which at some time exhibit evidence of renal disease. There are probably many patients in whom the kidney escapes damage altogether. But taking the evolution of a case which terminates in uræmia, following progressive destruction of the renal substance, the patient will exhibit—

1. A stage in which there is hyperpiesis, with a systolic pressure in the neighbourhood of 200, left-sided ventricular hypertrophy, and probably no other sign or symptom for many years. The effects of such an abnormality may lead to cardiac failure or cerebral hæmorrhage, but these complications are outside our present survey and we will confine our attention to those cases in which the kidney suffers.

This being so, our patient will pass on to—

2. A stage in which the progressive disease of the arterioles in the renal tissues is beginning to reduce the areas of effective kidney substance to a pathological degree. The patient's condition is now similar to that of an animal in

* Lectures I. and II. appeared in THE LANCET of March 17th and 31st, pp. 535 and 637 respectively.

which more than half, but less than three-quarters, of the renal substance have been extirpated. The number of functioning glomeruli and tubules is so reduced that the kidney cannot excrete its full quota of urea in fully concentrated form, but it is able to do so provided that such urea can escape in a dilute condition. There are, accordingly, no changes in the blood chemistry but a polyuria is present, and by day and by night the patient passes large quantities of urine of low specific gravity containing a low concentration of urea. This is what Fishberg has designated "compensated renal failure."

From this stage the patient gradually passes on to—

3. A stage in which he cannot excrete all the waste products of protein metabolism, even in a dilute condition. He therefore continues to exhibit a urine of low specific gravity and fails to respond to tests such as the urea-concentration test. But, in addition, he has an increasing retention of nitrogenous substances in the blood, and this nitrogen retention becomes more and more marked, is accompanied by phosphate retention, and finally by a retention of substances such as chloride which normally exhibit but little concentration during their passage from blood to urine. He dies in uræmia, and at the autopsy small red contracted kidneys are found.

These, then, are typical examples of arterial hypertension with renal disease, and they are to be regarded as cases in which a progressive narrowing of the arterioles has produced secondary disease of the kidney, and the following conclusions emerge:—

1. On available evidence we must believe that "chronic interstitial nephritis" so-called, and essential hypertension are different stages of one and the same disease.

2. In this disease hypertension always precedes, and often by many years, all clinical signs of renal damage. In the later phases hypertension is found associated with all grades of renal insufficiency.

3. The anatomical change found post-mortem in this disease consists of: (*a*) a generalised sclerosis of the arterioles; (*b*) cardiovascular hypertrophy; (*c*) varying degrees of ischæmic destruction of the renal tissues.

4. Renal sclerosis is part of a generalised vascular change, and is in all probability neither an early nor even an essential part of this vascular change.

5. Hypertension and diffuse sclerosis of the arterioles must be considered as associated manifestations of a single disease, though at present we are unable to prove that hypertension is either the cause or the effect of these vascular changes.

(B) THE RENAL COMPLICATIONS OF PREGNANCY.

In discussing this branch of our subject we are again confronted with difficulties of nomenclature. During pregnancy a series of complications is frequently encountered, ranging from the appearance of a slight albuminuria with no other sign or symptom, to severe albuminuria, œdema, marked elevation of blood pressure, and generalised convulsions. Cases with convulsions are almost invariably labelled as eclampsia, and though it is well recognised that œdema may be absent in such cases, eclampsia can never occur without some of the phenomena—albuminuria, œdema, or hypertension—which are usually accepted as placing a case in the category of renal disease.

It has often been suggested that eclampsia is merely uræmia occurring in the course of a complicated pregnancy, and if we accept the thesis that uræmia is a term covering several different conditions, there seems no sufficient ground for excluding eclampsia from the definition. It is, at any rate, sure that eclampsia is merely a name given by obstetricians to a clinical syndrome in which certain manifestations due to a renal disorder, and severe generalised convulsions, make their appearance at some time close to the moment of parturition.

Certain observers, such as Lubarsch and Fahr, and more recently Berkeley, Dodds, and Walker, have held that eclampsia differs from ordinary renal disease in that there is an important element of hepatic disorder always present, but though it is accepted that many eclamptic cases give evidence of a disturbance of the liver, the recent observations of Cruickshank, Hewitt, and Couper on 69 cases suggest that such signs of hepatic disturbances are relatively uncommon in this syndrome.

Whether cases exhibiting jaundice or other signs of hepatic disorder can properly be included under the heading of eclampsia, or whether, on the contrary, the term eclampsia should be reserved solely for such cases, it seems abundantly clear that at the present date we must continue to class together all the cases in which convulsions are combined with certain renal signs during the period of parturition, and when for the purpose of our present inquiry we ask what the relation of this state is to increased blood pressure, we must accept it as established that an elevation of the blood pressure is almost invariably present.

Examination of a large series of cases, such as that of Cruickshank and his co-workers, shows that this increase in blood pressure is not usually excessive, the systolic pressure being generally in the region of 160 mm., reaching 200 in perhaps 20 per cent. of cases, and being below 140 in a further 20 per cent. In general it appears to be established that the prognosis becomes worse in cases where hypertension is most marked. When these cases are examined after parturition it is found that in the majority of them the blood pressure quickly falls to normal, but the elevation may persist or even increase, and I have attending my out-patients' at Middlesex Hospital several patients in whom hyperpiesis has persisted for years after this complication of pregnancy.

Turning now to the renal complications of pregnancy in which convulsions do not occur, we may first of all exclude a large group in whom the presence of albumin in small amounts in the urine is the sole evidence of any abnormality, but having done this there remains a very numerous class in which albuminuria is accompanied by œdema in varying degree, often with headache or vomiting or cerebral symptoms indicative of a severe general disturbance. It has become customary to classify some of these cases as "pre-eclamptic toxæmia" and others as "nephritic toxæmia," but after prolonged and careful investigation of many of such cases, and a study of the literature dealing with them, I have never been able to discover any logical means by which an individual case can be placed in one or other of these groups. It rather appears that the method adopted is for the surgeon in charge of the case to call a case pre-eclamptic toxæmia when he has the impression that without treatment convulsions would have occurred, and to class it as nephritic toxæmia if a history of scarlet fever or the appearance of blood and casts in the urine, or some other manifestation, gives him the impression that the strain of the disease has fallen with particular acuity upon the kidney. In the same way it must be agreed that in series into which prolonged investigation has been made, such as that incorporated in the report to the Medical Research Council to which I have made reference above, one often finds classified as simple albuminuria cases in which œdema and sometimes a definite elevation of blood pressure was present and which, therefore, would appear to fall more properly into one of the other groups. If we look upon these cases as a whole, we find that some elevation of the blood pressure is present in the majority of them, if the cases where albuminuria is the only symptom are excluded, and in the group, which, to my mind for purely arbitrary reasons, has been labelled nephritic toxæmia the average blood pressure is very little, if at all, lower than in those with eclampsia. Indeed, it may be said that examination of the reports on such cases leaves the impression that a high blood pressure is one of the chief determining factors which leads to the inclusion of a case in the so-called "nephritic" group.

One must conclude that a moderate degree of hypertension is found in a high proportion of these cases, also that though such elevation of the blood

pressure is frequently transient there is a definite residuum of cases in whom it persists for years afterwards, and possibly for ever.

But a far more important problem arises at this point, it is this: Does the hypertension seen in the renal complications of pregnancy occur as a result of the complication, or was it present prior to the occurrence of any other symptom? To this all-important question I am unable to find a reply. I have the impression, and I think it is a general impression, that the hyperpiesia does not occur until albuminuria or some other evidence of renal involvement is present. But it is quite possible that it occurs at an earlier date, and it seems certain that in some proportion of these cases it was present even before pregnancy. We can draw no final conclusions from these cases until we are better informed concerning this point, and particularly it seems to me that the answer to this question will supply us with the all-important information as to whether hyperpiesis persisting after pregnancy is the result of a renal complication of pregnancy or is to be regarded as a separate disease.

The Term "Toxæmia of Pregnancy."

I have long felt that as physicians we owe a debt to the obstetric surgeons and their assistants who have made such careful inquiry into these problems, even though they remain in many ways mysterious. It is, indeed, unquestionable that we already possess many data from these cases which we should be glad to have in the case of similar purely medical ailments, and there is much to be said in favour of the attitude which persists in classifying such cases as "toxæmia of pregnancy," for that term tends to keep in view the general nature of the disease or diseases, in which clearly the renal manifestations are but a part of the whole.

The morbid anatomy of the kidney tends to show that the lesions present are of an almost purely degenerative character and the almost constant presence of œdema is—if the conclusions of my previous lectures are to be accepted—evidence of the coexistence of an important extra-renal factor It is perhaps of interest in this connexion to note that Petersen and Lash have observed an increased permeability of the capillaries in pregnancy, pointing to an important extra-renal factor always present in this state.

It is not my intention to-day to enter into any discussion of the pathogenesis of the renal complications of pregnancy. It seems, indeed, far too soon to endeavour to draw any conclusions on this subject, but we should, I think, bear in mind that Volhard and other German workers believe that a general spastic contraction of the arterioles is the most important factor in the production of all the manifestations of such disease. Volhard believes that in eclampsia and in convulsive uræmia generally, there is an œdema of the brain due to contraction of the arterioles, that such œdema is followed by compression of the capillaries and cerebral anæmia, and that this is the cardinal cause of the fits.

It may be that as Elwyn has suggested, following the ideas of Gaskell, an increased irritability is physiologically present in the pregnant uterus, and that such increased irritability is part of a similar condition present throughout the vegetative nervous system, and that hence there is an increasing tendency to vasoconstriction throughout the course of pregnancy.

"The possibility for the occurrence of arterio-spastic contraction lasts as long as these mechanisms retain their increased irritability. This is probably until the uterus is completely involuted. For this reason eclampsia may still occur in the puerperium."

Looking back over this subject, the following conclusions may be drawn:—

1. A moderate degree of hyperpiesis is found in about half the cases where pregnancy is complicated by albuminuria and œdema.
2. When eclamptic convulsions occur such hyperpiesis is present in a still larger proportion of cases.
3. The degree of hyperpiesis is some index of the severity of the case.
4. The raised blood pressure does not persist in the majority of cases which recover.
5. There is insufficient evidence as to whether the hyperpiesis appears before or simultaneously with the albuminuria and œdema.
6. It is not possible to form an opinion as to whether the hyperpiesis is the cause or the effect of such renal lesions as occur.

(C) Acute Glomerulo-nephritis.

We now come to acute nephritis of the type that occurs as a complication of scarlatina and other infections. There is to-day almost a consensus of opinion that such acute nephritis takes one of two forms: (*a*) that which is known as the focal type, in which the inflammation of the glomeruli is limited to a certain proportion of the total kidney substance; and (*b*) a diffuse type in which all the glomeruli are uniformly involved with a varying degree of inflammation.

The former type is probably more frequently associated with diseases such as acute tonsillitis and pharyngitis, and is frequently characterised by a considerable degree of hæmaturia. Owing to the limitations of the amount of kidney substance involved, there is seldom any noticeable reduction in renal function, and the course of the disease tends to be benign. Œdema and hypertension are probably always absent.

In sharp contrast to this, the acute diffuse glomerulo-nephritis usually makes its appearance in the second or third week of an infectious fever, and though the disease is of a far more serious character hæmaturia is seldom marked and streptococci, which are usually to be found readily in the urine of patients of the previous class, can seldom be demonstrated in this disease. It again contrasts with the focal type in that œdema is usually present to some degree, and in that an elevation of the blood pressure is frequently remarked.

It is regrettable that precise data concerning our immediate problem are even more difficult to obtain in these conditions than in the case of the renal complications of pregnancy. This is probably due in a large measure to the fact that these cases are usually segregated in fever hospitals. One would imagine that this very fact might favour the acquisition of scientific information, but unhappily this is not so at present.

In any case, the information concerning the incidence of hyperpiesis in acute glomerulo-nephritis is to-day lamentably inadequate. Christian and O'Hare state that in only 19 of 55 successive cases of this disease was there any increase in the systolic pressure, and in all cases in whom that pressure exceeded 180 or more they consider that a chronic nephritis had been present prior to the acute attack.

So far as it is possible to draw conclusions, one may perhaps say that:—

1. A moderate degree of hyperpiesis is found in a small proportion of cases of acute diffuse nephritis; it is by no means an invariable feature.
2. Œdema is probably an accompaniment of all such cases.
3. The blood pressure returns to normal in the majority after the subsidence of the acute attack.
4. Cases with a greater degree of hyperpiesis are probably those in which this condition was present prior to the acute attack, and in such cases high blood pressure will persist.

Chronic Diffuse Glomerulo-nephritis.

It is when we consider the chronic state into which many of these cases of acute nephritis pass that we enter into the most mysterious portion of the whole of the difficult subject of nephritis. There can be no question but that recurrent attacks of acute inflammation of the renal tissues are seen in an appreciable number of such cases, and it is usual for

such attacks to be accompanied by œdema and for the degree of hypertension to increase with each successive attack. In the course of time a permanent reduction in renal function becomes apparent. Polyuria is present because the concentrating power of the kidney is lost, and from this the patient passes to a stage of uncompensated renal failure, when nitrogen retention in the blood is present.

In the course of this evolution it is usual for a progressive elevation of the blood pressure to occur, but the figures seldom reach the height seen in the primary hyperpiesia which produces granular kidney as a terminal event. But although these cases of chronic glomerulo-nephritis usually exhibit progressive hypertension with cardiac hypertrophy, it must be recognised that there are certain rare exceptions. Thus Jores, Foster, Bouchut, and Bannick have all reported cases of well-marked chronic glomerular nephritis in which there was typical nitrogen retention, and, following death from uræmia, the kidneys were of typical fibrotic appearance, although there had never been elevation of the blood pressure during life and the heart was not enlarged.

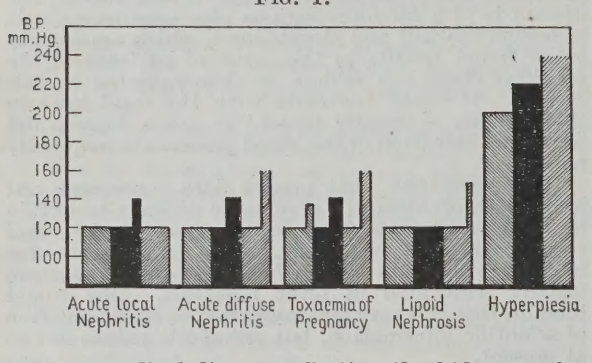
We must, I think, conclude that :—

1. In cases where diffuse glomerulo-nephritis becomes chronic there is usually a progressive elevation of the blood pressure.

2. This hyperpiesis very seldom, if ever, reaches the high degree found in cases of "essential hypertension" and is occasionally completely absent.

I have endeavoured in the diagram (Fig. 1) to set out the nature and incidence of hypertension in the

FIG. 1.



common medical diseases affecting the kidney as far as one can form an opinion in the light of our present incomplete knowledge. For each main group I have drawn three columns of which the central one represents the blood pressure when the case comes under observation as an example of "nephritis," the columns in the left of this being the tension before this period and the right hand column the subsequent finding. The relative breadth of each column shows roughly in what proportion of cases the blood pressure is abnormally affected. Thus you will note that I have tried to indicate that in acute diffuse nephritis a transient hyperpiesis, affecting a moderate proportion during the attack, becomes a permanent hyperpiesis in a few cases. In the toxæmias of pregnancy such cases probably include some who exhibited hypertension before ever their pregnancy occurred. In lipoid nephrosis, hyperpiesis is so rare as to make the accuracy of the original diagnosis doubtful, whilst in the group which is usually labelled chronic interstitial nephritis, the hyperpiesia long preceded the renal manifestations.

CAN RENAL LESIONS CAUSE HYPERPIESIS?

A question of paramount importance now presents itself. It is this: Have we evidence on which we can affirm that a renal lesion can by itself produce an elevation of the blood pressure?

On physiological grounds one would expect the answer to be "yes." A certain pressure in the renal arterioles is a necessity if the glomerular filter is to remain effective, and when a number of glomeruli are incapacitated by disease an increased pressure would seem to be needed if the remainder are to carry on their work effectively.

It must, of course, be borne in mind that like other essential organs, the kidney possesses considerable powers of reserve. The classical experiments of Rose Bradford demonstrated that it was necessary to remove three-quarters of the total kidney substance before renal failure was established, and the repetition of these experiments by Janeway and others has tended to show that such successive reductions in the renal tissue are accompanied by a moderate elevation of the blood pressure.

The question cannot be accepted as finally settled even to-day, for Anderson failed to produce hypertension by similar experiments on rabbits even when large amounts of the kidney substance had been removed, and permanent nitrogen retention with slow death had been produced. By giving high protein diets to such animals this observer was able to produce nitrogen retention even when as small an amount as 12 per cent. of the total kidney substance had been removed, but again there was no hypertension though extensive atheroma of the aorta was produced in many of the animals. We may perhaps assume that further evidence produced by ingenious experiments will finally demonstrate that destruction of sufficient renal tissue is followed by a rise in the blood pressure; the balance of evidence is probably in this direction even to-day.

But even if this be the fact, we are still far from knowing the mechanisms by which such hyperpiesis is produced. I will not detain you by going into details concerning the many negative observations which characterise the chemical side of such investigations; suffice it to say, that none of the nitrogenous constituents of the urine has been shown to increase the blood pressure when present in excess in the blood, and many hundreds of observations testify to the fact that such things as urea, uric acid, creatinin, chlorides, phosphates, and so on can exist in excess in the blood stream for months or years without producing high blood pressure.

Cholesterol has been the subject of particular inquiry in this respect, but it is now generally agreed that though atheroma and other degenerative changes in the arteries can be produced by cholesterol, excess of cholesterol in the blood is more characteristic of cases of lipoid nephrosis with a normal blood pressure than of cases of renal failure with hypertension.

The search for a pressor substance in the kidney itself is a chapter in the history of medical investigation which so far tells a tale of failure. Investigation, however, continues, and it seems likely that the future will demonstrate that hypertension in some degree can be a direct result of nephritis and renal disease. We must, however, recognise that the evidence points to such hypertension being only slight in degree and that when any patient exhibits an extreme degree of hyperpiesis a systolic pressure, for example, in the region of 200 or higher, that fact is strong evidence for the existence of an extra-renal factor; and, indeed, in any such case the probability will be that such renal damage as may be present is the result and not the cause of the morbid vascular change to which the high blood pressure is due.

THE NEED FOR A WIDE OUTLOOK.

I would like to conclude these lectures on Some Problems of Nephritis by emphasising the necessity of considering nephritis from a very broad point of view. Few organs in the body are exposed to so many influences of potentially dangerous character as is the kidney. It is perpetually exposed to attack from bacteria which may invade the blood stream, or which may with equal danger reach it via lymphatics or the ureter. It is also called upon to play an important part not only in the excretion of waste products from the blood, but in the adjustment of the proper balance between acid and alkali in the blood-stream and one has only to examine the work

of Nuzum or a score of other observers to realise how readily damage can be produced by chemical products from even normal foodstuffs when these are given in excess.

My friends, Prof. E. C. Dodds and Dr. S. Baker, working in the laboratories of the Middlesex Hospital, were, some years ago, able to establish the fact that an injection of hæmoglobin in the blood stream of a rabbit would produce fatal renal damage if the animal's urine was acid, but was innocuous when such urine was in an alkaline condition. Here again is an illustration of how apparently slight chemical factors may influence the pathology of the kidney.

L. S. Debenham, J. Joffe, and M. S. Pembrey demonstrated to what a striking degree the renal secretion can be affected by influences such as heat and cold directed to the skin surface of the body. So delicate is this response of the kidney to vasomotor changes in the capillaries of the skin that it is very probable that a so-called nephritis may accompany excessive stimuli or actual disease of very distant parts of the circulatory system.

I show you here two pictures (Figs. 2 and 3) which at first may appear entirely irrelevant to our subject, but this is not so, for they reveal to you the conditions prevalent amongst the patients on whom Bright made his famous observations. The pictures are from George Cruikshank's famous series entitled "The Bottle," and there can be little doubt that they express in dramatic, but not exaggerated form, the extent to which alcoholism prevailed in this country at that period. It seems to me not unlikely that this ætiological factor explains to some extent the differences shown in Bright's "Reports of Medical Cases" from the pictures of nephritis which we are accustomed to see at the present day. This impression is strengthened by reading the text of these reports, a typical example being that of—

FIG. 2.

From a print by George Cruikshank in his series entitled "The Bottle." "Between the fine flaring gin palace and the low dirty beer shop, the boy thief squanders and gambles away his ill-gotten gains."

"Henry Izod, a Smithfield drover, a man of very irregular habits who had long been accustomed to getting intoxicated with porter, but had only taken spirits to excess for the last year, during which time he had generally lodged at a public-house and had been exposed in his work to the inclemency of the weather, seldom wearing a hat, never changing his clothes when wet, and being almost daily intoxicated."

Surely it is not unnatural to suppose that a dietetic exuberance of this degree may have played an important part in the pathology of that epoch, and I make the suggestion to remind you of the wide view we must take of all cases to which the narrow definition of nephritis is applied. For such chemical influences as may affect the kidney will also throw a load upon extra-renal tissues, and especially on those of the circulatory system, and I have tried to show you how the study of uræmia involves inquiry into very broad biochemical principles, how œdema is probably always an index of damage to tissues outside the kidney, and how hyperpiesia is more often a cause than an effect of nephritis.

In a famous lecture Sir William Gull spoke as follows:—

"It is always dangerous to rest under a narrow pathology; and I believe that it is a narrow pathology which is satisfied with what you now see before you on this table. In this glass you see a large hypertrophied heart and a very contracted

FIG. 3.

Another print from "The Bottle." "Neglected by their parents, educated only in the streets, and falling into the hands of wretches, who live upon the vices of others, they are led to the gin shop, to drink at that fountain which nourishes every species of crime."

kidney. This specimen is classical. It was, I believe, put up under Dr. Bright's own direction and with a view to showing that the wasting of the kidney is the cause of the thickening of the heart. I cannot but look upon it with veneration, but not with conviction. I think with all deference to so great an authority that the systemic capillaries, and, had it been possible, the entire man, should have been included in this vase, together with the heart and the kidneys, and then we should have had, I believe, a truer view of the causation of the cardiac hypertrophy and of the disease of the kidney."

His words applied to cases of hyperpiesia with secondary destruction of the kidney, but the same broad outlook should be employed when regarding every type of renal disease.

HÆMOLYTIC STREPTOCOCCAL INFECTIONS IN THE RABBIT.

MOST workers would probably agree that the rabbit is the most suitable laboratory animal for the investigation of streptococcal problems. In the rabbit it has been found that the pathogenic effects produced by strains of hæmolytic streptococci from scarlatinal and non-scarlatinal conditions do not appear to depend on the origin of the strain in terms of human disease. If small quantities of any of these streptococci are given intradermally, superficial streptococcal abscesses are produced; if larger quantities are injected or a more virulent culture is used, a spreading condition is produced which may be compared with cellulitis or erysipelas. We have found that the erysipelas-like lesions described by Birkhaug as characteristic of erysipelas strains can be produced by strains of hæmolytic streptococci of the most diverse origin. There has been no evidence of specific blocking of these skin reactions with any serum, although a neutralisation effect was obtained with antierysipelas sera which were kindly sent to us by Dr. Birkhaug or which we had ourselves prepared by Birkhaug's methods. The results with these sera were, however, in the end inconclusive, for interference with the development of skin reactions was frequently induced to the same extent by scarlet fever antitoxic and antibacterial sera, diphtheria antitoxin, tetanus antitoxin, and normal horse serum. The effect, therefore, could not be ascribed to a specific antibody.

Fatal Septicæmia due to the Streptococcus of Scarlet Fever Controlled by Streptococcal Antitoxic Serum.

In previous papers it has been shown that many strains of hæmolytic streptococci from cases of scarlet fever are lethal for rabbits if given in suitable doses, and that this effect can be controlled by the intravenous injection, 4 to 6 hours before the culture, of streptococcal antitoxic serum, but not of sera other than streptococcal (Parish and Okell, 1927). Thus, young broth cultures of the scarlet fever streptococcus (S.F.1), given intravenously, kill rabbits with considerable regularity, the majority dying of acute septicæmia within a few days. Of 120 rabbits which received normal horse serum, concentrated diphtheria or concentrated tetanus antitoxin 4 to 6 hours before the injection of culture, only 20 per cent. survived for 48 hours and 6 per cent. for 6 days (Table I.).

TABLE I.

Rabbits injected intravenously with 10 c.cm. of 20-hour digest broth cultures of the scarlet fever streptococcus (S.F. 1). Antitoxic serum given intravenously 4 to 6 hours previously.

* Stage of immunisation.

Unconcentrated scarlet fever antitoxin in doses of 5 c.cm. or less, and concentrated† antitoxins of average potency in doses of 0·25 c.cm. to 1 c.cm., given intravenously, afford considerable protection against the acute phases of the septicæmia, although the majority of rabbits develop a subacute infection towards the end of the first week or later. This is characterised mainly by arthritic lesions from which hæmolytic streptococci can readily be recovered. Protection has never been obtained against this phase of the infection with any antitoxic or antibacterial serum we have used.

Many antistreptococcal sera, other than scarlatinal, prepared by the immunisation of horses with filtrates of hæmolytic streptococci have some protective properties in doses of 5 c.cm. or more. Experiments have been carried out with 14 unconcentrated and 4 concentrated antitoxins prepared from pyogenes, puerperal fever, and erysipelas strains. The percentages of rabbits which survived for 6 days ranged from 21 per cent. of those injected with unconcentrated erysipelas to 66 per cent. of those injected with

† By "concentrated" serum is meant serum from which as much as possible of the albumin and euglobulin has been removed by the well-known ammonium sulphate method. It usually represents a three- to four-fold concentration of the protective antibody.

concentrated pyogenes antitoxins. The protection given by the various sera correspond roughly to the amount of streptococcal antibody which they might be expected to contain from collateral evidence. The filtrates which were prepared from pyogenes, puerperal fever, and erysipelas strains, and which were used for the immunisation of horses, were weaker than those from the scarlet fever streptococcus (S.F.1) as judged by skin reactions in human subjects. It should be emphasised here that we have never been able to demonstrate in any type of experiment that the serum of rabbits highly immunised against washed (toxin free) streptococci, and often rich in agglutinins, has any protective properties. This probably explains the slight protective value shown by most of the older types of horse serum, used in the treatment of human streptococcal infections, which was usually prepared in response to injections of the bacillary bodies.

Deaths due to Scarlet Fever Toxin Prevented by Streptococcal Antitoxin.

Streptococcal antitoxic sera protect rabbits from deaths due not only to culture but also to scarlet fever toxin (Table II.). Although rabbits readily succumb to 5 to 10 c.cm. of young digest broth cultures of many strains of scarlet fever streptococcus, much larger doses—20 to 40 c.cm. given intravenously—of culture filtrates (without preservative), containing at least 15,000 human skin test doses per c.cm., are necessary to ensure deaths within 24 hours. Control injections of 60 c.cm. of the tryptic digest broth used for the preparation of toxin produced only temporary ill-effects. The toxin is almost completely inactivated by heating to 95–100° C. for 3 hours; 5 of 7 rabbits injected with 40 c.cm. of the heated filtrate survived. When scarlet fever or other streptococcal antitoxin is given intravenously 4 to 6 hours before the injections of toxin the majority of rabbits can be protected, but, owing no doubt to the fact that the test animal is relatively insensitive to the toxin, the results obtained are so irregular that it has not been found possible to use this method as a practical means of titrating antitoxin in the laboratory. From Table II. it will be seen that, as a group, the concentrated scarlet fever antitoxins afforded better protection than the various puerperal, pyogenes, and erysipelas antitoxins which were available for the experiments. Concentrated diphtheria antitoxin and concentrated tetanus antitoxin had no protective value.

The experiments which have so far been described demonstrate that sera prepared by immunising horses with filtrates of cultures of hæmolytic streptococci

from scarlatinal and non-scarlatinal conditions afford some protection against living cultures of scarlet fever streptococci and their toxins.

Protective Action of Streptococcal Antitoxin against Fatal Septicæmia due to Various Hæmolytic Streptococci.

The acute fatal septicæmias produced in rabbits by strains from cases of acute infectious pharyngitis, suppurative lymphangitis, malignant endocarditis, puerperal fever, erysipelas, &c., can be controlled by scarlet fever antitoxin, and by serum made from toxins from other strains of hæmolytic streptococci. In these experiments the infecting dose for the rabbit ranged from 1 to 20 c.cm. of 9 to 20 hours tryptic digest broth cultures of hæmolytic streptococci from various sources. The dose selected, which was almost always from 1 to 5 c.cm., depended on the virulence of the organisms, and probably represented in most experiments from 2 to 5 times the "minimal lethal dose" for the majority of animals. Serum was given in doses of 5 to 15 c.cm., usually 5 c.cm. in the case of concentrated antitoxins, and 15 c.cm. of unconcentrated antitoxins. It will be seen from Table III. that scarlet fever, and to a lesser extent other streptococcal antitoxic sera, have considerable protective effect against hæmolytic streptococci of diverse origin, the acute septicæmia which follows the intravenous inoculation of the culture being modified, as in the first series of experiments, into a subacute infection of which arthritis is the most prominent feature. Nearly all the strains have been tested for their ability to produce streptococcal toxin as demonstrated by a Dick test on human subjects, and have been proved to be capable of so doing to a greater or lesser degree.

In Table IV. the results of experiments recorded in Table III. are summarised with reference to the relative protection given by scarlet fever and other streptococcal antitoxins. As shown by the percentages of the total rabbits injected which survived for 3 and for 6 days, scarlet fever antitoxin was of greater value than any of the various samples of erysipelas, puerperal fever, and pyogenes antitoxins which were used for this work.

Summary.

1. Hæmolytic streptococci obtained from various sources—scarlet fever, erysipelas, cellulitis, puerperal fever, &c.—produce similar lesions of a pyogenic nature when injected intradermally in rabbits. We have been unable to demonstrate that sera prepared against either toxin or bacterial bodies contain a specific antibody which will prevent the development of the pyogenic skin reactions.

2. Scarlet fever and other streptococcal antitoxins protect rabbits from the acute phases of the septicæmia following the intravenous injection of the scarlet fever streptococcus, and from deaths due to scarlet fever toxin.

3. They have also a significant protective action against the septicæmia due to hæmolytic streptococci from conditions other than scarlet fever.

4. All hæmolytic streptococci appear to be identical in their "toxic" action. There is strong evidence that the protective action of streptococcal antitoxic sera is due to one antitoxin, which has been produced in horses in varying degree in response to immunisation with toxic filtrates of varying potency.

II.

THE RELATIONSHIP OF SCARLET FEVER TO OTHER STREPTOCOCCAL INFECTIONS.

BY C. C. OKELL AND H. J. PARISH.

IN the preceding communication attention was drawn to experiments in rabbits which suggest that hæmolytic streptococci from various human diseases may give rise to clinical conditions in the rabbit, independently of the source of origin of the strain, but depending upon its virulence, the site of inoculation, and the state of immunity of the host, and that such effects as are neutralisable can be neutralised by one antitoxin. In this paper we wish to elaborate this conception and discuss some of its clinical implications.

The Essential Similarity of Hæmolytic Streptococci from Different Sources.

To the hæmolytic streptococci are ascribed certain so-called "specific" diseases such as scarlet fever and erysipelas, and conditions such as cellulitis, puerperal fever, and acute pharyngitis which are not usually looked upon as specific. Many unsuccessful attempts have been made to classify the hæmolytic streptococci; morphologically and on biochemical grounds they are indistinguishable, and it is becoming increasingly obvious that they do not lend themselves to being classified in terms of the diseases they produce. Work on the agglutination reaction has elicited many interesting facts, some of which may have a practical application, but, as in the case of the diphtheria and tetanus bacilli, no evidence has been produced so far to show that there is any subclassification of taxonomic importance.

It has been shown that the specific signs of scarlet fever, the so-called "scarlatinoid syndrome"—rash, albuminuria, and even hæmaturia—can be produced in susceptible human subjects as the result of an injection of sterile scarlet fever toxin. If we take the symptoms due to the toxin away from scarlet fever we are left with a well-known clinical condition—viz., acute infectious streptococcal angina. Many cases of sore-throat without rash simulate scarlet fever in their infectiousness, severity, and complications. Some of these are found to propagate scarlet fever, and can be called "scarlet fever sine eruptione." As a rule, however, they propagate sore-throat and not scarlet fever, yet the streptococcus that causes them has all the essential properties of a scarlet fever streptococcus. This is illustrated by the following case.

A child caught an acute pharyngitis from a case of sore-throat. The onset was sudden with high fever, frequent pulse, and furred tongue; the infection spread rapidly and relatively painlessly to both middle ears. The child gave severe sore-throat to two individuals; no rash, however, appeared in any case. An almost pure culture of hæmolytic streptococci grew from the swabs of all three cases. The interesting point in this outbreak was that all the streptococci were fairly good producers of Dick toxin in vitro. The clinical condition was scarlet fever without scarlatinal toxæmia; a toxin was obtained from the streptococci which, had it been injected into the patient, would have produced a disease clinically identical with scarlet fever. The potentiality for producing the complete scarlet fever syndrome was there, but for some reason the particular strain of streptococcus, while a reasonably good toxin producer in vitro, could not produce any significant quantity in vivo.

The production of Dick toxin is by no means a peculiarity of scarlet fever strains, and results are rapidly accumulating which suggest that one toxic product can be obtained to a greater or less degree from many, if not all, human hæmolytic streptococci, which is indistinguishable from Dick toxin by the usual tests. A few workers—e.g., Kirkbride and Wheeler, 1925—have suggested a plurality of toxins, but the results can probably be interpreted as due to quantitative rather than qualitative differences between the toxins. It must be admitted that, if scarlet fever is due to a specific streptococcus, the only means of identifying the streptococcus is by the impracticable test of its power to produce infectious scarlet fever with rash in susceptible human subjects.

We are led to the conclusion that the ordinary conceptions of the specificity of the streptococcal diseases are well worth challenging. We suggest the hypothesis that the various streptococcal infections are all due to essentially the same species of bacteria. Their pathogenic effect varies with certain accidental factors, mainly quantitative, such as invasiveness and toxigenicity on the part of the strain and local or

general susceptibility on the part of the host. We thus attempt to revive and extend views often held in the past and to ascribe the differences in the human diseases due to hæmolytic streptococci to variables which, though little understood, are at least universally allowed to both parasite and host. We do not wish to minimise the clinical nor even the epidemiological differences between the streptococcal diseases. Our purpose is rather to explain a maximum number of facts on a minimum number of suppositions; in other words, to formulate a working hypothesis which will serve as a basis for further work and at the same time suggest a rational therapy of the streptococcal diseases. In the following table an attempt is made to apply these ideas to some of the clinical entities due to infection with the hæmolytic streptococcus. The sign + in the first column indicates that the streptococcus produces enough toxin to produce a rash if the patient is fully susceptible to Dick toxin. By ± is meant that, though the streptococcus probably produces a certain amount of toxin in vivo, it does not produce sufficient to give rise to obvious clinical signs of scarlatinal toxæmia. The degree of infectiousness is roughly indicated in the second column.

Toxigenicity of streptococcus in vivo.	Infectiousness.	Location of infection.	Susceptibility of patient to Dick toxin.	Disease.
+	++	Throat.	+	Scarlet fever.
+	++	,,	−	Acute infectious pharyngitis.
±	++	,,	+ or −	
±	+	Skin.	+ or −	Erysipelas; cellulitis.
+	+	Uterus.	+	Puerperal fever with rash.
+	+	,,	−	Puerperal fever without rash.
±	+	,,	+ or −	

Under a "unitarian" theory the relationship between puerperal fever and puerperal scarlet fever becomes more defined. The known clinical entities can be divided into:—

1. Primary faucial infection with rash and with secondary infection of the uterus.

2. Primary infection of the uterus with a streptococcus of any origin which is markedly toxigenic in the uterus—usually without secondary faucial involvement.

It may be mentioned that all the puerperal strains we have examined have been able to produce Dick toxin in vitro.

According to such a view a streptococcus from a scarlet fever case might, under suitable conditions, produce erysipelas or puerperal fever or cellulitis, and vice versa a hæmolytic streptococcus associated with any disease, if it underwent the requisite modification in virulence and toxigenicity, might be conceived as producing scarlet fever and maintaining this capacity during a considerable epidemic period. It is by no means unusual for an epidemic of scarlet fever to start with atypical cases, slowly to attain to normal clinical pathogenicity, and then to fade away again to atypical cases before it suffers extinction. Goodall and Washbourn in the 1896 edition of their "Manual of Infectious Diseases," p. 330, state:—

"When looked at from a clinical point of view, erysipelas appears at first sight to be a definite specific disease with characteristic symptoms. Nevertheless, there are many facts in connexion with its ætiology and pathology which show that it cannot be considered on quite the same footing as other specific fevers. The latter diseases are specific in the sense that they "breed true." A case of rubeola, for example, will in other persons give rise only to rubeola, and not to any other disease. A case of erysipelas is often the origin of erysipelas in other patients, but under certain circumstances it may cause an entirely different type of disease. Nurses suffering from erysipelas have conveyed puerperal fever to lying-in women, and medical men and nurses have contracted erysipelas when in attendance upon cases of puerperal fever. Moreover, a comparison of the registered deaths from erysipelas, puerperal fever, and pyæmia shows a sufficient correspondence to suggest that a relationship between these diseases exists. Again, a true cutaneous erysipelas cannot be sharply separated from phlegmonous erysipelas; nor can the latter disease be always separated from allied septic inflammations."

Several other authors have drawn attention to the close correspondence between the annual and seasonal incidences of the deaths from scarlet fever, erysipelas, and puerperal fever—e.g., Longstaff, 1891, Geddes, 1912 and 1926. McKinlay (1928), however, does not consider that this correspondence should be taken as supporting the idea of a common ætiological factor.

One more piece of evidence in favour of the unity of erysipelas streptococci with the other hæmolytic streptococci has recently been produced by the Dicks (1927), who have succeeded in producing experimental sore-throat by painting erysipelas streptococci on the throats of human volunteers.

As we pointed out in the previous paper, the results of our experiments in rabbits are at variance with those of Birkhaug. The erysipelas-like lesions in the rabbit are produced by all the strains we tried, whatever their origin. The peculiarity of the lesions was, so far as we could judge, entirely dependent on the virulence of the strain used and the layer of the skin that was injected.

One Identifiable Therapeutic Antibody to Hæmolytic Streptococci, generally known as Scarlet Fever Antitoxin.

It may be asked in what way this "unitarian" theory of the hæmolytic streptococci would modify existing views on the specific treatment of streptococcal disease. It has been our experience that all hæmolytic streptococci make the same toxin and that there is only one identifiable antibody—namely, what is generally known as scarlet fever antitoxin. The antitoxins produced in horses by injecting filtrates of streptococci from scarlet fever, puerperal fever, septic wounds, and other conditions, are qualitatively indistinguishable; but since scarlet fever strains are usually more active toxin producers in vitro, the highest grade sera are made in response to injections of their filtrates.

We ascribe the pathogenic activities of the hæmolytic streptococci to (1) their invasive function, over which the antitoxin has only a limited control; and (2) their toxigenic function, which the antitoxin has full power to neutralise. In our rabbit experiments we were unable to discover a specific method for neutralising the invasion of the skin with hæmolytic streptococci. In human subjects a limited anti-invasive property is shown by the fact that those who have been protected with the antitoxin do not take scarlet fever, and usually show no signs of infections with the streptococci, although it is believed that under certain conditions a sore-throat can be produced in Dick-immune persons (Stevens and Dochez, 1926; Nicholls, 1926; Kinloch, Smith, and Taylor, 1927). It is generally admitted that the septic complications of scarlet fever are very little affected by antitoxin treatment. In the rabbit the development of arthritis is uninfluenced by the injection of serum, even in large doses.

We would lay particular stress on the observation, already referred to in the first part of this paper, that an acute and rapidly fatal septicæmia in the rabbit may be converted by antitoxin into a subacute and relatively benign infection. It is probable that some degree of scarlatinal toxæmia is present in all streptococcal infections, although it may not be obvious clinically. For example, the salmon-pink lymphatics occurring in acute cellulitis are undoubtedly due to the removal of Dick toxin along these channels, and the appearance can be closely imitated by injections of sterile Dick toxin.

It seems obvious that, since so-called scarlet fever antitoxin is the only demonstrable therapeutic antibody to the whole group of hæmolytic streptococci, it should be used in all streptococcal infections,

particularly in acute septicæmias where there is a demand for serum treatment. We have already seen a limited number of clinical reports claiming that excellent results have followed treatment with scarlet fever serum in such conditions as puerperal septicæmia, septicæmia from wounds, and erysipelas. It is true that we cannot attach much importance to isolated clinical trials, but it is interesting to know that the evidence, such as it is, points to a common therapeutic antibody. One special application for the streptococcal antitoxin would be its use in the prophylactic treatment of wounds received while performing post-mortem examinations or septic surgical operations, in the hope of being able to parallel the rabbit effect and prevent the development of a fatal septicæmia.

Conclusions.

1. The hæmolytic streptococci of human origin represent one species of bacteria with common pathogenic potentialities. The balance of "phasic variations" on the part of the bacterium with local and general susceptibility on the part of the host would explain the apparently "specific" clinical conditions which result from infection.

2. A single antitoxin generally known as scarlet fever antitoxin corresponds with the single toxin. This may be depended upon to neutralise the specific toxæmia, and possibly has limited anti-invasive properties as well. It is the only streptococcal antibody with any acceptable experimental and therapeutic credentials, and should be given a more extensive trial in all severe streptococcal infections, particularly in general septicæmia. It is also suggested that it should be used in the prophylactic treatment of wounds received while performing post-mortem examinations or surgical operations on septic cases.

THE TREATMENT OF COMPLETE RETENTION OF URINE OF PROSTATIC ORIGIN BY ELECTRO-COAGULATION.

By J. G. REMIJNSE,
HEAD SURGEON TO THE COOLSINGEL HOSPITAL, ROTTERDAM.

In the *Nederlandsch Tijdschrift voor Geneeskunde* of June 11th, 1927 (p. 3228), Dr. J. A. Weijtlandt describes a patient, 76 years of age, who suffered from prostatic disease, which had caused complete retention of urine within a very short time. Dr. Weijtlandt treated this man successfully by diathermy applied through McCarthy's cystoscope, and by so doing showed that this method of treatment deserves general attention as much for its thoroughness as for its simplicity and lack of danger. It is a treatment which will probably find considerable scope in the near future. I have therefore been encouraged to publish the results obtained by us at the Coolsingel Hospital in the treatment of prostatic diseases with electro-coagulation, although we are well aware of the fact that the time that has elapsed since we started this mode of treatment is altogether too short for us to regard the results obtained as final. The provisional outcome, however, is so encouraging that others might find it worth while to add this new application of the high-frequency current to their surgical arsenal. I do so the more readily since electro-coagulation in other departments of surgery has yielded such valuable results; for example, in the treatment of cancer of the tongue and the oral cavity, growths of the vocal cords, breast, womb, and many other organs. In reports of these treatments it has been asserted that: (1) operative damage could be considered of small importance in comparison with that of other surgical methods of treatment; (2) bleeding could be fully controlled; (3) scars, as the result of the coagulation, are supple; (4) a subsequent operation by the same or by a different method is not impossible.

By surgical diathermy with a blunt electrode tissue can be either heated en masse, even as far as boiling-point, after which the necrotic tissue is cast off spontaneously, or it can be severed with a thin needle.

Our treatment of the hypertrophic prostate aimed at the massive necrosis, as did Weijtlandt's, although the methods differ considerably in many respects. Up till now we have treated with electro-coagulation 52 patients suffering from disease of the prostate. Four have died; in 8 cases the treatment has not yet ended or no good results are evident; all the others benefited greatly by this simple treatment, inasmuch as all of them could urinate very well after the treatment. Originally we submitted to this treatment only those patients for whom operation with the scalpel was deemed too dangerous—e.g., very old people, those suffering from heart disease and diseases of the blood-vessels, and more especially those with deficient function of the kidneys.

The Operative Treatment.

We make it a rule in the Coolsingel Hospital that prior to all prostatectomies the function of the internal organs, and especially those of the kidneys, shall be improved as far as possible by preliminary treatment, and we consider that the lowering of the nitrogen percentage of the blood serum, which is nearly always greatly increased at the time of admission, is of the utmost importance.

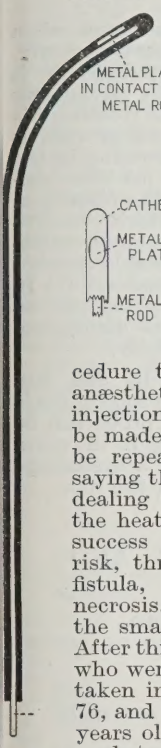
We insist on a sequence of treatments, such as irrigation of the bladder, self-containing catheter, diet, drugs and complete rest, until a series of consecutive tests have shown the urea percentage to be about 350 mg. per litre, or less, and not until then is prostatectomy considered justifiable. We have reason to be very satisfied with this mode of preliminary treatment, the operative mortality being 1 case in 50 prostatectomies. All the others came through the operation very well and were dismissed completely cured. A certain number of patients, however, can never be treated by operation, even after a prolonged sojourn in hospital. It is not to be wondered at that we looked for other means to give relief to those "stayers" with their total obstruction, to try to enable them to live outside the hospital without the self-retaining catheter. This means we think we have found in electro-coagulation with the diathermy apparatus.

In February, 1927, we had in our wards two patients 77 and 80 years old, who had been there for quite a number of months and who showed all the symptoms of a prostatic hypertrophy dating from a long time back. One of them had been operated upon for diverticulum of the bladder and vesical calculi. Both were suffering from emphysema of the lungs, arterio-sclerosis, and cystitis. The complete retention had persisted, notwithstanding dieting, irrigation of the bladder, and the self-retaining catheter. One had a small, the other a large, prostate. Both suffered from boils and showed a high urea percentage in their blood. In February, 1927, we coagulated the prostate in both cases; the patient with the enlarged prostate was submitted to two subsequent treatments in February and March; the patient with the small prostate was given one more treatment, but not until May, because he had developed an epididymitis. Both patients left the hospital in good condition, able to pass water spontaneously, although a small amount of residual urine still remained.

Technique.

The procedure which we followed differed from that of Weijtlandt. We used an active electrode introduced into the urethra, in the shape of an ordinary French catheter, with a strong curve, such as that in vogue for catheterisation of patients with enlarged prostates. Inside the catheter was a metal rod which, through a hole near the end of the catheter, was in contact with a metal plate. The outside surface of this plate was on a level with that of the catheter, which was made of insulating material (Fig. 1). The probe is introduced in the usual way into the urethra, and the right forefinger, slipped into the rectum, controls with exactitude the position of the top of the catheter and the plate in relation to the prostate, the plate being brought opposite the posterior lobe. The large, flat, indifferent electrode is placed under the patient's buttocks, and the diathermic current of ½–1 ampère is switched on. In this way an exactly definable part of the prostate is heated, and the degree of heat can be controlled by the finger in the rectum. As soon as the finger feels a slight heat the current is turned off. The whole procedure takes one minute at the utmost, no anæsthetic being required, unless a preliminary injection of 10 c.cm. of 2 per cent. novocaine be made into the urethra. The treatment can be repeated if necessary. It goes without saying that one should be extra careful, when dealing with small prostates, not to extend the heating too long. It is better to obtain success in repeated sessions than to run the risk, through overheating, of a recto-vesical fistula, as the outcome of too extensive necrosis. For this reason the patient with the small prostate was treated several times. After this favourable outcome six other patients who were deemed unfit for prostatectomy were taken in hand, one of them being 64, another 76, and the remaining four between 80 and 84 years old. All of them showed total urinary obstruction, which remained after a preliminary treatment with the catheter. They were all dismissed, a few without any residual urine, one with a residual urine of 35 c.cm., and three with a residual urine of less than 100 c.cm. One of them needed only one treatment, four two treatments, and one three treatments. Between two consecutive treatments an interval of at least a week was observed. The patient aged 76 was thought to be suffering from a carcinoma of the prostate, judging from the nodular outline and hard consistency of the gland and from its lateral extension towards the pelvic wall. The others showed simple senile enlargement.

FIG. 1.



Introduction of the diathermy point does not differ from introduction of an ordinary catheter. Before treatment the bladder is washed out and 100 c.cm. of normal saline left behind. After treatment the self-retaining catheter is introduced. A few necrotic pieces of tissue are cast off in the course of the next few days. Within a fortnight after the first treatment spontaneous urination was often possible.

Abridged clinical histories of the eight patients treated by diathermy are given below.

CASE 1.—Aged 77 years. Admitted June 5th, 1926. So-called atrophic prostate. Complains of impaired urination for several years and total urinary obstruction since March. General condition very bad. Last July a diverticulum was extirpated and stones were removed. The total obstruction remained unchanged. Cystoscopic examination was frequently made. The total obstruction was caused by a small prostate with a small central lobe. In the end (Feb. 24th) diathermo-coagulation was performed, and repeated on March 4th and 16th. On March 24th the patient passed water spontaneously, at first rather little (250 c.cm.), so that catheter treatment remained necessary until April 15th, after which date all symptoms had disappeared, although a small quantity of residual urine remained (no more than 25 c.cm.).

CASE 2.—Aged 80 years. Admitted Oct. 7th, 1926. Suffered for a few months from trouble in passing urine, and for a few days from total obstruction. Diagnosis: Senile enlargement of the prostate, myocardial degeneration, bronchitis. Prostate about the size of an egg. Notwithstanding catheter treatment, total obstruction remained. The patient suffered from boils. April 7th, 1927, diathermo-coagulation. April 17th, passed urine spontaneously, no complaints, no residual urine.

CASE 3.—Aged 84 years. Admitted Dec. 27th, 1926, with a history of urinary obstruction for one month, becoming complete a few days before admission. Prostate moderately enlarged; catheter treatment without effect. March 6th, epididymitis. May 7th, diathermo-coagulation. May 24th and June 2nd, repeated. June 7th, urinated spontaneously. June 10th, dismissed with small amount of residual urine, about 50 c.cm.

CASE 4.—Aged 84 years. Admitted Jan. 11th, 1927, with total obstruction, bronchitis, emphysema, and irregular heart action. Prostate large, irregular. From Jan. 11th to Feb. 25th treatment with self-retaining catheter. Total obstruction remained. Feb. 24th, diathermo-coagulation. March 6th, catheter withdrawn, spontaneous urination, no retention. Discharged free from symptoms.

CASE 5.—Aged 64 years. Admitted Feb. 2nd, 1927. Three years pollakiuria; for one year complete retention, for which he himself applied a catheter rather frequently, not forgetting to lubricate the beak with saliva before introducing it. Large, dense, irregular prostate. Self-retaining catheter up till March 24th. On this day first treatment with diathermo-coagulation. April 6th, spontaneous urination. Residual urine 35 c.cm. Passed water easily, no complaints.

CASE 6.—Aged 81 years. Admitted April 12th, 1927. Five years' history of obstructed urination, total obstruction for eight days; arterio-sclerosis; herniæ; large, dense prostate. After short treatment with self-retaining catheter and irrigations with nitrate of silver, without obvious effect, treatment with diathermo-coagulation on two occasions. The last time was May 19th. On May 20th discharged free from symptoms and without any residual urine.

CASE 7.—Aged 80 years. Admitted Feb. 14th, 1927, from the medical department, where the bladder was daily emptied for total obstruction. Large prostate, compact. Feb. 17th, diathermo-coagulation. Feb. 24th, catheter removed. Passes a little urine. Again diathermo-coagulation. April 6th, all complaints vanished. Discharged, but a residual urine of nearly 100 c.cm. remained, which has since disappeared altogether.

CASE 8.—Aged 76 years. Admitted April 16th. History of urinary trouble for a few months and total obstruction supervening shortly before admission. Diagnosis: Carcinoma. Prostate irregularly enlarged, with lateral extensions towards the pelvic wall; bronchitis, arterio-sclerosis, hernia. March 24th, diathermo-coagulation. April 6th, first spontaneous urination. Further diathermy treatment. April 16th, no complaints. Residual urine about 100 c.cm. Discharged.

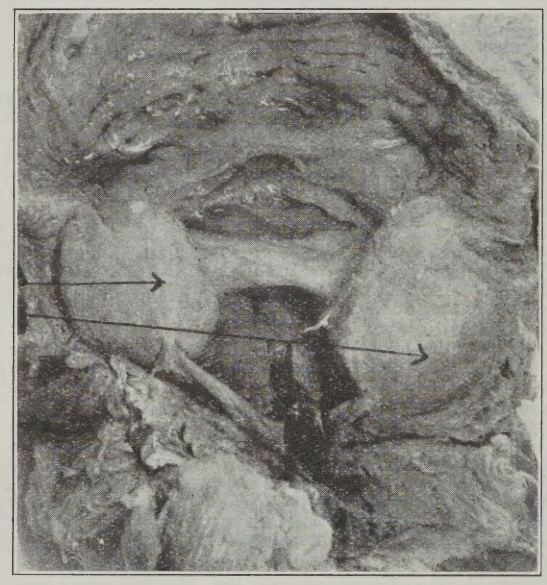
After these eight patients we treated all cases with total obstruction in the same way, and no more prostatectomies have been done. We can now record 40 cases, some of which were treated in the out-patient department. The treatment is extremely simple and there is very little chance of annoying surprises, provided we take the necessary precautions and accurately locate on the introduced forefinger the place for the active electrode (the plate) and discontinue the process of heating after one minute. Introduction of novocaine in the urethra sufficed as an anæsthetic, although it is not necessary. There was hardly any pain during the treatment, provided the electrode was properly situated. The mucous membrane on the far side of the pars prostatica is more sensitive than the pars prostatica itself. We never noticed any bleeding; even in those cases where catheter treatment caused bleeding it stopped immediately after coagulation. Incontinence of urine never occurred.

Routine Treatment.

With an ordinary catheter we empty the bladder, the bladder is washed out, and 100 c.cm. of normal saline is left behind. The catheter is withdrawn and the probe

introduced. With the forefinger in the rectum the exact position of the plate (the active electrode) opposite the posterior lobe, is controlled, and the current (which should not exceed 1 ampère) is turned on and applied during no more than one minute. The probe is moved slowly up and down to ensure application to the full length of the pars prostatica. When heat is felt, the current is turned off, even when the treatment has lasted less than one minute. Sometimes the moment coagulation is effected, one feels a peculiar purring sensation at the end of the probe, coinciding with an immediate drop of the ampère-indicator; it is then time to remove the electrode (probe) further up or down, in order to coagulate a fresh part of the prostate. The probe is withdrawn and the self-retaining catheter put in in its stead. The bladder is washed out daily, and after eight days we take the catheter out and wait to see if spontaneous

FIG. 2.



The arrows point to the separated lobes of the prostate.

urination occurs. If not treatment is repeated, if necessary more than once, but always observing an interval of at least one week. Meanwhile the bladder is daily emptied with the catheter until spontaneous urination manifests itself. At first it may happen that the patient cannot fully empty his bladder. In that case the treatment should be repeated until the residual urine is reduced to about 50 or 60 c.cm. Coagulation is then no longer necessary, and all that remains to be done is daily irrigation of the bladder to make the residual urine disappear altogether.

It is too early to claim ultimate cure, but even if later on it appears that no cure was obtained, a repetition of the treatment would be feasible. At any rate, we prefer this treatment to the dangerous and bloody operation with these very old patients, having a bad general condition. Moreover, the method is new and the instruments improvised, and improvements are certainly possible.

Complications.

1. *Death.*—Four patients have died. Twice we had the opportunity of observing the results of our coagulation in post-mortem cases a few weeks after the last treatment. One of the patients died from a general infection following introduction of a fresh catheter, when a false passage was made. The other died from perforation of an infected diverticulum of the bladder. Both patients had already passed urine spontaneously for a number of weeks. They were still under treatment for cystitis. At the autopsies the prostate showed a deep, wide furrow in its posterior part, which caused the two lobes to be well separated (see Fig. 2). It was evident that the central part of the prostate had disappeared altogether through coagulation. The two other patients died from pneumonia and emphysema.

2. *Cystitis.*—Most of the patients already have cystitis before the treatment; if not, in most cases the treatment by catheter and diathermic probes is followed by cystitis.

3. *Epididymitis.*—Epididymitis is often seen. It occurred in 10 of our 52 cases; in a few cases an abscess from a purulent epididymitis followed, and necessitated incision. In the other cases an ice-bag only was used, with good results.

4. *No result.*—In three cases spontaneous urination is not obtained after five or six treatments on account of atonic detrusor.

Summary.

Surgical diathermy will gain in importance when we have had more experience in managing it properly. For the treatment of prostatic hypertrophy it is undoubtedly of the utmost value. The advantages of this method are the following: (1) The treatment is not very dangerous. (2) It can be executed without pain after preliminary injection of novocaine in the urethra. (3) There is no bleeding. (4) The procedure is under continuous control of the forefinger. (5) All kinds of prostate trouble which involve retention can be tackled, even the atrophic prostate. (6) This method can replace a considerable number of otherwise unavoidable prostatectomies. (7) In cases in which operation cannot be carried out on account of the bad general condition diathermo-coagulation can still be applied successfully.

Note.—The probe is manufactured by the firm Krupp (Essen). The metal part of the probe is made of stainless steel, and the curve of the probe can be modified to some extent after heating it in warm water. Another probe has the form of a cystoscope with the plate on the inner surface near the top.

MULE-SPINNERS' CANCER AND MINERAL OILS.

BY C. C. TWORT, M.D. ABERD.,
PATHOLOGIST TO THE MANCHESTER COMMITTEE ON CANCER;
AND
H. R. ING,
CHEMIST TO THE MANCHESTER COMMITTEE ON CANCER.

THE experiments to be described were undertaken with special reference to mule-spinners' cancer of the scrotum, but at the same time samples of oils other than those used in the cotton-spinning industry were tested. It has already been shown by Leitch that shale oil is far and away the most toxic of the lubricating oils, while the crude petroleum oils, which this worker obtained from many oil-fields in different parts of the world, are relatively little capable of exciting the development of malignant tumours. It will be found that, in the main, our results confirm those of Leitch. The material utilised by us consisted chiefly of purified oils or oil blends actually used for the lubrication of the mules in the spinning rooms. It has not always been an easy matter to discover the actual source of some of the samples, but in many cases this does not appear to be of great importance in the present state of our knowledge. As far as can be seen at present the lubricating oils tested by us can be divided into three groups according to their carcinogenic action.

1. Sperm oil, which appears to be harmless.
2. Natural petroleum oils, which are but little carcinogenic.
3. Shale oils, which are very carcinogenic, and seem to act as a weak tar.

It remains to be seen whether at a later date we shall be able to show that oils from some fields are consistently more toxic than oils from certain other fields, or whether it is only the refining processes undergone by the oils to which any difference in them is really due.

In each of our experiments 100 mice were used, the oil being applied to the skin of the back with a camel-hair brush twice weekly. The following oils have been tested :—

1. A blend of a purified American petroleum oil and 10 per cent. sperm.
2. A pure American petroleum oil.
3. A pure, refined, heavy Pennsylvanian petroleum oil.
4. A pure, refined, light Pennsylvanian petroleum oil.
5. A pure, refined Californian petroleum oil.
6. A pure, refined Texas petroleum oil.
7. A pure, refined shale oil.
8. A pure, refined sperm oil.
9. Waste oil from wool mule-spinning machines.
10. Waste oil from cotton mule-spinning machines.
11. A highly refined liquid paraffin.
12. A light machine oil, as used for sewing machines.

Nos. 1 and 2 were obtained direct from the cotton-spinners. Nos. 3–8 were guaranteed samples, kindly supplied to us gratis by an oil blender, and were oils used for blending spindle oils. Nos. 9 and 10 were collected by us from the oil-saturated waste material on the spinning machines.

The results of these experiments will be found in Table I. It will be seen that the shale oil applications led to the development of a very much greater number of tumours than any of the other oils, and that the first wart and the first epithelioma appeared at an earlier date. The six American petroleum oils gave occasional tumours, but usually only after the lapse of a considerable time. One of them—viz., No. 6, the Texas oil—has, up to the present time, given no sign of leading to the development of a tumour. On the other hand, the Californian oil has given quite a number of tumours. Although the experiment lasted for 73 weeks, No. 1 oil gave only a solitary epithelioma, and that in the fifty-third week.

Ep.* = Epithelioma. Ep.† = Epitheliomata.

The oils Nos. 1–12 correspond to Nos. 1–12 in the text. The proportion of shale oil tumours to petroleum oil tumours is 17 to 1. The average time for the development of the first wart and first epithelioma with the petroleum oils was at least 35 and 51 weeks respectively, as against 17 and 26 with the shale oil.

In view of the long duration of these experiments with oils an attempt was made to concentrate the toxic material in the oils. Several methods were tried, but the only one which will be mentioned here is that of fractional distillation. In these preliminary experiments the oils were divided into two fractions and no refractionations were made, and at the same time only two oils, Nos. 1 and 2 in the list, were tested. We have in progress, however, many additional experiments of this nature, the results of which will be discussed at a later date.

The results with oils Nos. 1 and 2 will be found in Table II., and it is obvious that in these two oils the heavy fraction is the more carcinogenic, while the lighter fraction appears to be less toxic than the original oil. Oil No. 1 was distilled at atmospheric pressure, the lighter fraction coming over between 355° and 385° C., and the heavier from 385–420° C. Oil No. 2 was distilled under a pressure of 12 mm. the lighter fraction coming over between 240–300° C., and the heavier from 300–360° C. Of course, in all such experiments it is necessary to be certain that there is no fabrication de novo of the carcinogenic substances during the manipulations to which the oils are subjected. Control experiments with this object in view are now under way, but they are not yet far enough forward for any conclusions to be drawn from them.

TABLE II.—*Distillation of Oils.*

2. Heavy „ ..	23rd	18th	10	11	50

Proportion of tumours in animals treated with heavy fractions to tumours in animals treated with light fractions is 31 to 1.

Freeing Oils from the Carcinogenic Factor.

Finally, a few words may be said on attempts which we have made to free oils from their carcinogenic substance or substances. The methods used were :—

1. Extraction with sulphuric acid.
2. Extraction with methyl sulphate.
3. Extraction with methyl sulphate and picric acid.
4. Extraction with methyl sulphite.
5. Oxidation by means of pure oxygen at 150° C.
6. Reduction by means of amyl alcohol and sodium.

Only the sulphuric acid experiments have been in progress sufficiently long for us to be able to draw our final conclusions, but we can already say of the remaining five that they have at any rate reduced the carcinogenic power of the oils. (N.B.—No. 6 experiment was performed with a synthetic tar in place of an oil.) As was expected, the results with the sulphuric acid, which will be found in Table III., showed most conclusively that the acid purified the oils of their toxic power to a remarkable degree. It remains to be seen, however, whether the oils are entirely freed of their carcinogenic principle or principles, and concentration of the sulphuric acid-treated oils are now being carried out in order to investigate this point. Incidentally, these purification experiments have been undertaken with the object of trying to get an indication of the nature of the toxic substance or group of substances responsible for the production of the malignant tumours. Our results all seem to suggest that the unsaturated hydrocarbons and the aromatics are the substances which first need investigation.

Total tumours among 400 animals. { Sulphuric acid-treated oils = 0; Controls .. .. .. = 92

An endeavour was made to produce tumours in mice by the subcutaneous and intraperitoneal injection of many petroleum and other oils. Although many of the animals among the 357 utilised survived for over a year, all have so far been negative. However, 75 of the animals are still alive.

Conclusions.

1. A few tumours, some of them histologically malignant, have developed on mice subjected to the skin application of petroleum oils as used in the cotton-spinning industry.

2. Passage of such oils through the machinery does not appear to render them more carcinogenic.

3. The higher boiling fractions of the two petroleum oils tested were much more carcinogenic than the lower boiling fractions. Tumours were in the proportion of 31 to 1.

4. Shale oil, which is obtained by the destructive distillation of shale, appears to be much more dangerous than the petroleum oils obtained from wells. Tumours were in the proportion of 17 to 1.

5. The purification of the oils by means of sulphuric acid renders them practically harmless. In our eight experiments the treated oils led to the development of no tumours, as against 92 tumours in the controls. Experiments on other methods of purification are mentioned.

6. The subcutaneous and intraperitoneal injection of many different oils failed to excite the development of tumours.

VARIATIONS IN THE VOLUME OF THE CHEST WITH CHANGES OF POSTURE.

By J. L. LIVINGSTONE, M.D., M.R.C.P. Lond.,
SENIOR MEDICAL REGISTRAR, KING'S COLLEGE HOSPITAL.

WHILE house physician to Sir Charlton Briscoe I assisted him in some observations upon the variations of the level of the diaphragm in normal individuals. These observations were carried out by X ray examination, both in the usual method of a direct antero-posterior view and also by taking observations of the level of the diaphragm where it left the chest wall in the post-scapular lines, and in the nipple line on the right side anteriorly. The position of the heart prevented a corresponding observation on the left side. These observations showed that the diaphragm is at its lowest position in the thorax when the subject is erect, at its highest when he is supine, and intermediate when he is reclining at an angle of 45°. The changes in level occur rapidly with changes of posture. Further, when changes of posture occur, the diameters of the chest undergo alterations. Measurements were taken at the levels of the upper and lower ends of the gladiolus (the joints between the manubrium and gladiolus and between the gladiolus and xiphisternum) and at the lowest border of the thorax all in the mid-axillary line. These transverse measurements are increased when the patient assumes a reclining or supine posture. The change is not so rapid from erect to supine as it is from supine to erect. The antero-posterior diameter at the level of the lower end of the gladiolus is also increased in a similar manner; that at the upper end of the gladiolus varies, being sometimes increased and sometimes diminished.

In view of these changes in the diameters of the chest and the level of the diaphragm, it was not possible to foretell whether any change would occur in the volume of the thorax. A change in volume would offer an explanation for postural deflation, and might conceivably offer some explanation for the different postures adopted by patients suffering from heart lesions. It was in the hope of throwing some light on the latter that this work was undertaken.

Methods.

Those who have had experience of volumetrical work on the respiratory system know how difficult it is to get a subject to breathe naturally through a valve, and what varied results may be obtained. In these experiments every precaution was taken to ensure uniformity of results. The normal subjects were students of the hospital. The observations were made at 9 A.M., shortly after breakfast. Practice breathing with the valve was undertaken on several occasions before the actual observation, and all changes of posture were rehearsed. Repetition of experiments showed a certain amount of variation; the changes, however, were all of the same nature, although the actual volumes varied. X rays show a definite and rapid alteration in level of the diaphragm on change of posture, usually within two to five breaths; in some postures the full degree of change is attained only after a much longer period. In the following experiments ten breaths were taken as covering a period in which a definite alteration occurred.

The following changes of posture were used :—

1. Lying supine to standing erect.
2. Standing erect to lying supine.
3. Lying supine to reclining at 45°.
4. Reclining at 45° to lying supine.
5. Reclining at 45° to sitting upright.
6. Sitting upright to reclining at 45°.

The apparatus was as follows :—

1. A hinged table upon which the subject can lie supine and which can be swung easily from the horizontal to the vertical position, with a foot-rest to stand on. This is used for changes 1 and 2.

2. A couch with a hinged back which can be raised quickly to make the subject sit at 45° and sit upright from the supine position, his legs being horizontal all the time. This is used for investigations 3–6.

3. A respiratory valve with a rubber flange mouth-piece and nose-clip, fitted with light rubber "flutter" or "disc" valves offering a minimal resistance and with a very small "dead-space." The valve is connected by two wide flexible tubes to two 10-litre bags of light mackintosh material. A two-way aluminium tap is fitted between each tube and bag, allowing the subject either to inspire from one bag and expire into the other through the valve, or to breathe in and out of the air of the room. The volume of air in the bags is measured by displacing an equal volume of water contained in a large carboy, and weighing the displaced water. The bags are emptied by sinking them with a leaden weight in a large tank of water; the pressure of the water on the outside, emptying the bags completely and uniformly, drives the air into a closed carboy. The water in the carboy is saturated with carbon dioxide to avoid loss of volume by solution of carbon dioxide; the air in the carboy at room temperature displaces an equal volume of water, which runs out into a vessel; the water levels are adjusted so that the pressure inside the carboy is at atmospheric pressure again, when the water ceases to run away; the displaced water is weighed.

On testing the apparatus without a subject breathing, the experimental error in measuring the volume of the bags was below 50 c.cm. (1 per cent.). With the subject breathing at a constant posture, the error was below 100 c.cm. (2 per cent.) for ten breaths.

The method of performing the experiments is as follows :—

Change to be recorded; from supine to vertical.

Having loosened all tight clothing, the subject lies supine upon the table; the mouth-piece and nose-clip are adjusted and, with the taps open, he breathes through the valve in and out of the atmosphere. A known volume of air is put in the inspiratory bag; the expiratory bag is emptied and the bags are attached, one to each tap. After lying supine for a few minutes to ensure a constant level of the diaphragm, the taps are turned at the end of an expiration, so that he inspires from one bag and expires into the other. After one breath the table is swung to a vertical position by an assistant; at the end of the tenth expiration the taps are turned off and the subject disconnected. The time taken for the ten breaths is noted by a stop-watch. The volume of air in the bags is now measured and the volume of inspiration and expiration for the ten breaths is calculated. The experiment is now repeated in the opposite direction, the subject first standing erect and then being swung into the horizontal position. The volume of inspiration and expiration is again measured. Intermediate postures are similarly investigated—i.e., from reclining at 45° to lying supine, or to sitting erect with the back resting against the couch, and vice versa. The figures of a typical experiment will illustrate the method.

Subject 1. Aged 25 years, normal.

Lying Supine to Standing Erect: Change 1.

	lb.	oz.	dr.
Inspiratory bag before experiment	16	0	12
Remainder in bag after experiment	1	4	0
∴ Volume of inspired air	14	12	12
Expiratory bag (empty before observation) after experiment	13	2	12
∴ Excess of *inspired* air	1	10	0
	= 737 c.cm.		

Standing Erect to Lying Supine: Change 2.

	lb.	oz.	dr.
Inspiratory bag before experiment	16	4	6
Remainder in bag after experiment	3	6	14
∴ Volume of inspired air	12	13	8
Expiratory bag (empty before observation) after experiment	14	4	4
∴ Excess of *expired* air	1	6	12
	= 644 c.cm.		

The weights given above are the weights of the water displaced by the air contents of the bags.

The results of these experiments on normal people show a definite and uniform change. Ten cases were examined in the major change of posture, from lying supine to standing upright and vice versa (changes 1 and 2). On assuming the erect posture there was an excess of inspiration varying from 493 to 1093 c.cm., with an average of 822 c.cm. On assuming the horizontal position there was an excess of expiration from 270 to 903 c.cm., with an average of 500 c.cm.

Five cases were examined in the first minor change from lying supine to sitting at 45° and vice versa (changes 3 and 4). This change was similar to the major change, except that the volumes were about half. On assuming the more vertical posture there was an excess of inspiration from 70 to 477 c.cm., with an average of 205 c.cm.; with the more horizontal posture there was excess of expiration from 31 to 150 c.cm., with an average of 94 c.cm.

Ten cases were examined in the second minor change, from sitting at 45° to sitting erect, and vice versa (changes 5 and 6). Here the results were not constant as in the other two changes of posture, for in five cases there was excess of expiration on assuming the more vertical position. The amounts of excess were small, averaging about 200 c.cm.

Conclusions.

The results in normal individuals show that the capacity of the chest is least when supine, greatest when erect, and intermediate in the intermediate postures. This corresponds with the alteration in elevation of the diaphragm, and not with the change in the diameters of the thorax. This change of volume occurs rapidly by the expulsion or retention of the air in the lungs—i.e., by expiring more than is inspired, or by inspiring more than is expired. The results are clear-cut in respect of changes arising when the posture is altered from supine to standing erect, or vice versa, and from supine to reclining at an angle of 45°, or vice versa. The slighter change of posture from reclining at an angle of 45° to that of sitting upright—i.e., moving the back of the couch against which the patient rests through an angle of 45°—gives a variable result, air being either retained or expelled. No reason for this is forthcoming. It does not appear to be due to the type of breathing, thoracic or abdominal, of which careful records were made.

The results show definitely that in normal persons the changes in level of the diaphragm are associated with a change in volume of the chest, which is mainly accommodated for by alteration in the balance between air inspired and air expelled.

Posture and Chest Volume in Heart Disease.

The cardiac cases were investigated only in the minor change of posture, from lying supine to sitting at 45° and vice versa (changes 3 and 4), as it is comparable in every way to the major change, and causes much less disturbance to the patients, many of whom were severely decompensated and unable to stand up. The results may be summarised as follows:—

Twenty cardiac cases were investigated. Of these, ten suffered from mitral stenosis in different stages of cardiac decompensation; they were all females, from 10 to 59 years of age. The remaining ten cases were instances of aortic regurgitation, seven male and three female, from 12 to 68 years. In seven the lesions were due to syphilis, in three they were of rheumatic origin. Normal results were obtained in seven of the mitral cases and decompensation was present in three of these. Abnormal results were given in three cases. The first was decompensated, but gave a normal result four weeks later, when compensation was restored; the second was a very nervous woman, who breathed entirely with the thorax and who refused to be reinvestigated; the third was a girl, aged 12 years, also rather nervous and a thoracic breather, who gave a similar result at a second examination. The results were normal in eight of the aortic cases, which included two decompensated hearts. Two cases were abnormal; the first was a boy of 12 years with a decompensated aortic and mitral lesion; the second was a man with a fairly large fusiform aneurysm of the aorta, with good compensation who breathed entirely with the abdomen. Five of the mitral and two of the aortic cases were uncomfortable lying supine, and one of these aortic cases was grossly decompensated. There was no constant difference in the type of breathing, whether abdominal or thoracic, in the two series of cases.

On examining the results of those observations in the two types of cardiac cases there is no experimental evidence to differentiate them from each other or from the healthy subject. It was thought worth while to record these findings, although they are negative.

Summary.

(1) With changes of posture of the body the diaphragm alters in level, making a difference in the volume of the chest; this difference in volume is mainly effected by alteration in the balance of the air inspired to the air expired. (2) A change in level of the diaphragm, on assuming a different posture of the trunk, takes place in less than ten breaths. (3) In wide changes of posture, from lying supine to standing erect, the difference of volume between inspired and expired air is large. In small changes of posture, lying supine to sitting at 45° and sitting upright to sitting at 45°, the difference in volume is smaller, corresponding roughly to one-half of that found in the full range of movement. (4) The experiments agree with the X ray findings. In the erect position the diaphragm is low and the intrathoracic volume is large; in the supine position it is high and the volume is diminished; sitting at 45° the diaphragm and the chest volume are intermediate in position and size. On sitting upright the level of the diaphragm varies somewhat with different individuals, and may approach the "high" or the "low" position. The volume shows corresponding changes. (5) No difference is found between the aortic and the mitral case. (6) The change in level of the diaphragm might well account for the "postural deflation" occurring in post-operative cases.

Since this work was completed two articles have been published which seem to confirm my findings.

1. W. A. Wilson,[1] working with a recording spirometer on normal subjects, finds that the volume of reserve air varies with posture, from 250 c.cm. lying supine to 1550 c.cm. standing erect.

2. J. R. Head,[2] working on the vital capacity of cases before and after surgical operations of all sorts, found that there was a reduction of the vital capacity in all cases from 5 to 80 per cent. The greater reduction occurred in cases where the respiratory muscles were injured, especially abdominal operations near the diaphragm. The time taken for the vital capacity to return to normal was proportional to the initial drop.

I have to thank Sir Charlton Briscoe for suggesting this research and for very helpful advice; I must also thank Prof. A. J. Allmand, of King's College, London, for advice as to methods, and Dr. R. Rutherford and Dr. J. N. Cumings, of King's College Hospital, for their valuable assistance in performing the experiments, and I am most grateful to the various students who gave up a good deal of time and suffered a considerable amount of inconvenience while being experimented on.

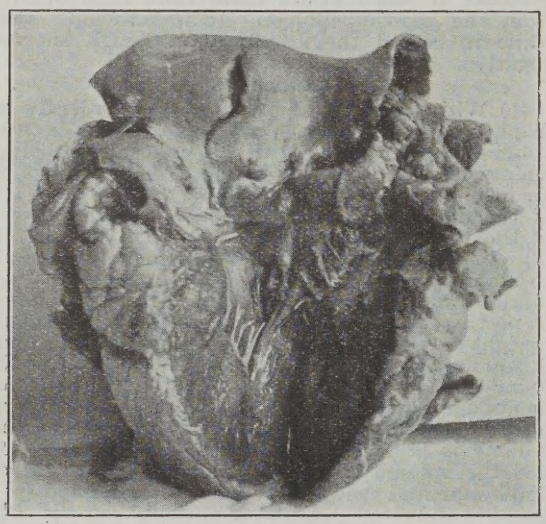
Clinical and Laboratory Notes.

A CASE OF SPONTANEOUS RUPTURE OF THE THORACIC AORTA.

By Frederick T. Thorpe, M.R.C.S. Eng.,
ASSISTANT MEDICAL OFFICER AND PATHOLOGIST, SOUTH YORKSHIRE MENTAL HOSPITAL, SHEFFIELD.

Complete rupture of the aorta without injury or severe strain seems sufficiently rare to justify description of the following case.

Clinical History.—The patient, a female, aged 82 years, was suffering from chronic mania. Her clinical records show that she had well-marked signs of arterio-sclerosis, with a double aortic and a mitral systolic bruit. Apart from general feebleness attributable to her age, she was comparatively well and able to occupy herself in the ward during the day. There is no history of angina, or of any



Complete rupture of the aorta.

symptoms leading up to the rupture. The Wassermann reaction was not performed.

On the morning of Feb. 1st she suddenly collapsed on getting out of bed, and died within a few minutes.

Post-mortem Examination.—The heart was normal in size; weighed 9¾ oz.; length from aortic ring to apex, 9 cm.; left ventricular wall, 2 cm. thick. The pericardial sac was distended and contained over 2 pints of fluid blood. The subpericardial fat was greatly increased; the muscular wall of the left ventricle firm and slightly hypertrophied. The aortic and mitral valves were thickened and showed evidences of chronic endocarditis. The first part of the aorta was not dilated to any noticeable extent and showed no gross atheroma, but the intima around the openings of the coronary arteries had a scarred and furrowed appearance.

There was a longitudinal split 3 cm. long situated just above the aortic valve and penetrating both intima and media. The blood had made its way between the middle and outer coats of the vessel wall, distending the adventitia for about 4 inches toward the arch, finally bursting into the pericardial sac. The transverse and descending parts of the aorta showed extensive atheroma with calcareous plaques specially round the orifices of the arterial branches. The kidneys were small, pale, and of the granular contracted type.

Stained sections of the ascending aorta showed atrophy of the intima and well-marked degenerative changes in the media. The adventitia was distended with blood-clot. The muscle-fibres of the myocardium were apparently healthy except for a slight increase of brown pigment around their nuclei.

Remarks.

According to most authorities spontaneous rupture of the aorta is rare and usually transverse. In this case it would appear that the sudden slight increase of blood pressure on getting out of bed was sufficient to cause the vessel wall to split longitudinally at the site of an intimal fissure, but it is also highly probable that the rigidity of the atheromatous arch was a factor in the production of extra strain upon the weakened first part of the aorta.

Sir William Osler[1] remarks that spontaneous rupture—

"may occur in a vessel apparently healthy, either as a result of a sudden strain or sometimes without any effort. . . . It has occurred in a healthy boy, aged 13, following prolonged exertion. . . . The rupture in the external coat is rarely directly opposite that in the intima, so that there is usually some evidence of dissecting aneurism. The cases present very characteristic features, the symptoms occurring in two stages . . . . one corresponds to the rupture of the intima, with which is associated the severe pain and collapse, from which the patient gradually recovers. Then in the course of three or four days external rupture takes place with sudden death."

In the present case, however, there were no premonitory symptoms suggesting the occurrence of these two stages, but it has to be remembered that subjective symptoms in the insane are often in abeyance.

I have to thank Dr. W. Vincent, medical superintendent, for permission to publish this report.

A CASE OF ELECTROCUTION
WITH NOTES ON THE CLINICAL VALUE OF LOBELINE.

By J. Gwynne Morgan, M.B. Lond., M.R.C.S. Eng.,
HON. MEDICAL OFFICER, CLYDACH HOSPITAL;
AND
Arthur J. Amor, M.B. Lond., B.Sc. Wales, M.R.C.S. Eng.,
MEDICAL OFFICER, MOND NICKEL CO., LTD.

The accident here described occurred to a healthy athletic young man, about 21 years of age, who was an assistant in the shop of an electrical engineer.

He was sitting in the workshop during his dinner hour, when his feet slipped from the edge of a table on which they were resting and knocked over an electric fire. The heating elements broke so that the metallic casing became alive and the lad's foot remained in contact with this for approximately one minute. The voltage was 220 and the current direct.

One of us (J. G. M.) was summoned at 1.45 P.M. and found the patient slightly cyanosed, sitting on a chair, in a stuporose condition. He complained of severe frontal headache and nausea, and later he vomited. He was placed in a comfortable position and treated for shock. His condition improved considerably until 3 P.M. when he suddenly became unconscious. He vomited again and developed considerable œdema of the lungs with irregular stertorous breathing, marked cyanosis, and a full bounding pulse. The right pupil was dilated and immobile, the left, pinpoint, and a divergent strabismus developed later. The corneal reflex was just present on both sides. In consideration of the irregular breathing, cyanosis and œdema of the lungs, gr. 1/100 of atropine sulphate and gr. 3/10 of lobeline hydrochloride were given intramuscularly. Oxygen was administered and as a result the breathing became more regular and deeper, the cyanosis improved and the œdema lessened. All the muscles of the body were now in a state of tonic contraction and about every five minutes a convulsion of both arms and legs occurred. At 4 P.M. the temperature had risen to 104° F., the pulse volume was still full, and the breathing was regular. The epileptiform spasms became less frequent, and at 6.15 P.M. the muscles of the arms and legs were flaccid, the pulse was rapid, and of small volume, while the respiration was of the Cheyne-Stokes type. A further dose of gr. 3/20 lobeline hydrochloride and gr. 1/60 strychnine was given, but unfortunately this was of no avail. Death occurred at 7.45 P.M.

Post-mortem.—There was no sign of an electric burn on the skin. On opening the skull there was intense vascular congestion of the dura mater, more noticeable on the left than the right. The cerebral vessels were similarly congested, there being free blood present with clots in the following positions: (1) around the medulla, (2) between the cerebellum and the tentorium, (3) over the island of Reil. Both lateral ventricles were full of blood-clot. On

[1] Osler and McCrae: Modern Medicine, 1927, vol. iv., p. 855.

microscopical examination of the cerebral cortex minute hæmorrhages were visible. The motor cells showed marked chromatolysis.

In their summary of the action of lobeline (THE LANCET, 1926, ii., 1255) F. R. Curtis and Samson Wright point out its value as a powerful respiratory stimulant, but suggest that caution should be exercised in use owing to its property of producing marked cardiac depression. During the past two years we have used lobeline "Ingelheim" on six occasions, both in adults and children, giving the doses recommended by the manufacturers—i.e., to adults gr. 3/20, and to children gr. 1/10. Our clinical experience agrees with their experimental evidence that lobeline is a powerful respiratory stimulant, but the only cardiac depressant action we have noticed is slight diminution in the pulse volume. In order to investigate any depression in the blood pressure, we submitted ourselves to intramuscular injections of 10 mg. of lobeline. Readings of the blood pressure and pulse-rate were taken every minute for between 20 and 25 minutes after injection and no marked lowering of the systolic blood pressure was noticed. In the case of one of us, the pulse-rate rose 12 beats per minute four minutes after injection and maintained this new rate for 16 minutes. In both cases a perceptible diminution in the pulse volume occurred between five and six minutes after injection.

P. Behrens and C. T. Pullwka [1] found that the blood pressure remained practically constant when using it experimentally on animals poisoned with carbon monoxide. We have not had the experience of giving two doses within an hour, but in all our cases it has produced the desired reaction, and we do not believe that its cardiac depressant action is sufficient to mitigate its value or seriously restrict its use.

A CASE OF SUBCUTANEOUS EMPHYSEMA COMPLICATING LABOUR.

BY M. SALMOND, M.D., B.S. LOND.,
SECOND ASSISTANT GYNÆCOLOGICAL AND OBSTETRICAL UNIT, ROYAL FREE HOSPITAL.

CASES of surgical emphysema occurring during labour are of sufficient rarity to warrant description of the following case which occurred in the obstetrical unit of the Royal Free Hospital.

A primigravida, aged 18, had a normal antenatal period except for slight bronchitis. She went into labour at full term and had a long first stage (55 hours). The second stage was also long (six hours). There was no maternal or fœtal distress and no interference was indicated. Two and a half hours before the child was born swelling appeared in the face extending from the cheeks to the neck. It was not tender and the patient only complained of slight discomfort. Later in the day after delivery the swelling was found to extend all over the face and chest. Typical crackling was present. There were a few scattered rhonchi in the chest. The swelling lasted for ten days. No special treatment was needed for the emphysema.

The puerperium was complicated by a *Bacillus coli* urinary infection. The patient made an uneventful recovery.

Dr. L. S. T. Burrell, who kindly examined the patient, found no lesion in the chest suggestive of tuberculosis and an X ray was normal. It is probable that during expulsive efforts a vesicle was ruptured into the mediastinum which caused the escape of air into the connective tissue planes of the neck. I have found five references [2] in recent English and American literature to a similar condition. In all these cases the emphysema caused no serious symptoms in itself and disappeared in about a fortnight.

I am indebted to Prof. Louise McIlroy for permission to publish this case.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

A MEETING of this Society was held in London on March 30th, Colonel L. W. HARRISON in the chair. A discussion on the

Antenatal Treatment of Gonorrhœa

was opened by Mr. EARDLEY HOLLAND, who gave an account of the views on this subject he had formed in the course of obstetric practice. He had been impressed, he said, by the rarity of gonorrhœa as a complication of pregnancy or the puerperium, both in hospital and private practice. Among 10,000 confinements at the City of London Maternity Hospital between 1922 and 1927 there were records of only eight cases of gonorrhœa, though a number of slight cases had probably been missed. There were only three cases of ophthalmia neonatorum, and though ocular instillation of silver nitrate was a routine of the hospital, the rarity of the condition was nevertheless striking. At the London Hospital, during 1926 and 1927, when there were 4200 confinements, there were only four cases of gonorrhœal ophthalmia. At that hospital there was a special ward of six beds for cases of puerperal septicæmia, and in this ward during the last 22 years there had been only one case of gonococcal septicæmia. During the six years from 1922, 99 pregnant women were sent to the hospital's venereal clinic on account of vaginal discharge, and only 28 of them could be proved to have gonorrhœa. These cases included many which had been sent in by general practitioners, and in the same period the deliveries at the hospital numbered 13,000. Mr. Holland thought there was a tendency to make a loose and facile diagnosis of the disease in pregnant women without sufficient data. Most midwives, he believed, considered that every woman who had an excessive discharge had gonorrhœa—a mistake which admittedly had the result of bringing all doubtful cases for treatment. He asked whether a coincident clinical infection of the urethra, Bartholin's gland and the cervix, with the presence of macules about the orifices of the urethral and Bartholin's ducts was sufficient to warrant a diagnosis of gonorrhœa. His own view was that this diagnosis should not be made unless the organism could be found—i.e., demonstrated by proper technique. He would not accept the diagnosis if the organism obtained did not grow on a medium favourable to the gonococcus, the culture tube being maintained at the proper temperature, remembering how susceptible the organism was to cold. A prevalent error was to regard the so-called venereal warts (condyloma acuminata) as pathognomonic of the disease, which they were not. On the other hand, many cases of gonorrhœa were sure to go unrecognised, because they presented few or no signs or symptoms. The vaginal discharge of many pregnant women was simply an excess of the normal discharge, and gonococcal cases were very liable to be regarded as normal for this reason. Gonorrhœa might seem to be common to the venereal expert, because he dealt only with this department, but it was rare in the population as a whole. To take cervical cultures from all pregnant women in order to avoid missing a case of the disease would be as unpractical as to make pregnancy notifiable in order that every woman should have a Wassermann test. The great need was to teach all in the profession to recognise suspicious cases. Most cases of gonorrhœa in pregnancy did not show the fully developed signs of the disease. It was of the utmost importance to treat and cure the disease before the woman reached term. Gonorrhœa was less dangerous during pregnancy than at other times, because the ovum intervened to prevent

infection of the Fallopian tubes from the infected cervix. The termination of pregnancy, however, was almost always followed by upward spread of the infection, which made it very necessary that diagnosis and treatment should be early. He asked whether gonorrhœa was more resistant during pregnancy than in the non-pregnant state. For many years practitioners had been afraid of carrying out vigorous cervical swabbings lest abortion might result, but he believed that, given reasonable care, this fear was groundless. He had never seen a case of abortion which might have been due to gonorrhœa.

Dr. F. H. LACEY began by speaking of the necessity for close coöperation between all maternity and child welfare clinics and venereal disease centres. Gonorrhœa had been much in evidence since the war, and women often did not seek relief, especially in the lower classes, because their symptoms were slight. This applied particularly to those in domestic service, who had, perhaps, only one free night weekly, on which no clinic might be open. He regarded antenatal work as the greatest advance in obstetrics during the last few years. In Manchester the out-patient departments of large antenatal clinics were in close touch with the venereal clinics, and women having a discharge which might be gonococcal were transferred to the venereal clinics for attention. It was difficult to treat a woman as an out-patient, especially when the husband refused to be treated. Often the husband's infection occurred during the last few weeks of his wife's pregnancy. When the diagnosis of her condition was in doubt, it was safer to regard her as infected. As regards treatment, when patients would not attend regularly, self-douching was better than no douching at all. He had been disappointed with vaccines, except in gonococcal rheumatism. Among 119 women suffering from gonorrhœa delivered in the last three years there had been no case of puerperal fever or ophthalmia neonatorum. He did not think that gonorrhœa played an important part in the causation of puerperal fever. Many women were infected by their husbands shortly after the puerperium, the latter having acquired the disease during the wife's lying-in. In a series of 375 cases of puerperal fever the gonococcus was found in only five, and in all of these recovery took place.

In conclusion, Dr. Lacey raised the question how the incidence of gonorrhœa among women could be lessened. He thought a great deal could be done by means of lectures to women, both married and single, on how venereal diseases were acquired, their symptoms, and their dangers. Special courses should be held for nurses and midwives. In view of the long hours worked by many women, courses late in the evening should be arranged, even as late as midnight.

Dr. F. J. BARKER contrasted the paucity of cases of gonorrhœa in obstetric practice, as given by Mr. Holland, with the prevalence of the disease 30 years ago as he had seen it, and remarked on the great reduction in the incidence of ophthalmia neonatorum. Before 1900 it was no exaggeration to say that 20 per cent. of the blindness of the world was due to gonorrhœa. The results of treating the disease in women were still discouraging and the greatest hope lay in prevention. Education was the chief need, and would do more than anything else to bring about a reduction of the disease. In cases where the Fallopian tubes were affected he pleaded for a more conservative line of treatment than removal of the tubes, which was done too ruthlessly by a certain school of surgeons. Careful, patient treatment would often lead to restoration of their function.

Dr. W. F. R. BURKE said that a good deal of gonorrhœa was seen in women who were not pregnant, and the facts seemed to point to a great amount of sterility being due to gonorrhœa. Very few would think of relying on clinical signs for a diagnosis of the disease; slides and cultures must be employed. In suspicious cases provocative measures should be adopted. He thought that if gonorrhœa was more often looked for in gynæcological practice it would be more often found.

Dr. C. A. NICHOLL said he had no facilities for making cultures, and he made his diagnosis of the disease by means of smears. He did not hesitate to pack a cervix for a long time; the only reason for not doing it was that abortion might take place.

Dr. B. B. SHARP said he seldom saw gonorrhœa in pregnant women; his experience was mainly with children. For them he found acriflavine inferior to protargol and glycerine, 10 per cent.

Dr. VIOLET RUSSELL, dealing with the question whether active treatment of the cervix was liable to cause abortion, said that at Guy's Hospital during seven years she had not seen one case of abortion which could be attributed to the treatment. There had, in fact, been very few cases of abortion associated with gonorrhœa. It was not the practice at Guy's to pack the cervix, but it was sometimes painted with strong antiseptics. Tampons were used, without detriment. Gonorrhœa was not, in her view, a more severe disease in the pregnant than in the non-pregnant women.

Dr. DOROTHY LOGAN expressed her surprise at the small amount of gonorrhœa met with by Mr. Eardley Holland among pregnant women. In her own small clinic at King's College Hospital the proportion referred to her from the maternity department was higher than he mentioned. She agreed with Dr. Russell's remarks about treatment of the cervix; she also agreed with Dr. Barker about the need for conservatism in treating disease of the tubes.

Dr. T. J. WRIGHT referred to a case of tubal disease in which the patient, being anxious to have a child, refused the surgeon's overtures to remove the tubes. Diathermy aided recovery, and 14 months later he learned that she had given birth to a child. He strongly disapproved of the great readiness of some surgeons to remove diseased tubes.

Dr. MARGARET RORKE thought that in some institutions the cervix was not examined as thoroughly as it should be. The suspected discharge sometimes proved not to be gonococcal, but simply an exaggeration of the normal discharge. She did not think the presence of warts in pregnancy indicated gonorrhœa, and she was certain that gonorrhœa did not cause abortion per se. Dr. Rorke had no criticism of gynæcological surgeons; her general experience of them was that they were conservative and very helpful.

Prof. F. J. BROWNE thought it wise to regard as gonorrhœal long-standing cases with excessive vaginal discharge and severe cervicitis, though they should not be so labelled. Really the only conclusive test of gonorrhœa in the female was her capacity to infect the male. In pregnancy the gonococci lay deep in the glands; they were easily killed if they could be reached with the antiseptics employed.

The CHAIRMAN thought that the decrease in the number of cases operated on for infected tubes, and the decrease of ophthalmia neonatorum, was evidence of the success of the treatment of venereal disease as a whole. He endorsed Dr. Lacey's plea for a close liaison between antenatal clinics and venereal disease departments.

Mr. EARDLEY HOLLAND, in reply, said he found pyosalpinx much less common now than 15 years ago; a similar remark was applicable to ophthalmia neonatorum. He thought the fewness of the recorded cases of gonorrhœa in pregnancy was largely due to many having been overlooked. He endorsed everything Dr. Barker said as to the importance of conservative treatment of Fallopian tubes infected by gonococci. Streptococcal infection, however, often needed operation, because of the risk of general peritonitis.

LONDON ASSOCIATION OF MEDICAL WOMEN'S FEDERATION.

Radium Treatment of Uterine Cancer.

A MEETING of this Association was held on March 27th at the house of the B.M.A., Miss ELIZABETH BOLTON, the President, being in the chair.

Miss M. CHADBURN gave an account of the work undertaken by the Cancer Research Subcommittee since its formation in 1925. It had been decided to concentrate on radium treatment of uterine cancer. The committee had spent the first few months studying technique, and continental clinics had been visited in order that different methods and results could be compared. Dr. Hurdon, the research officer for whose services a grant was given by the Radiological Committee of the Medical Research Council and the British Empire Campaign, had done magnificent work under great difficulties. The treatment was given at the four hospitals—the Royal Free Hospital, South London Hospital for Women, Elizabeth Garrett Anderson Hospital, and the New Sussex Hospital for Women—staffed by women, in coöperation with Dr. Hurdon, who advised them as to technique and followed up cases after treatment. The need for concentrating the work in one centre was becoming more and more apparent, though some cases would still be treated at these hospitals even when the ideal of a central institute had been achieved. It was estimated that £10,000 would suffice to make a modest beginning, and members of the association were urged to attempt to collect this sum.

Dr. HURDON pointed out that during the last few years radium had largely taken the place of surgery in the treatment of cancer occurring in accessible situations. In the Mayo and certain other clinics radium was now used exclusively for cancer of the cervix, even in operable cases. Statistics over a term of years would be necessary before the comparative results could be estimated, but at present it looked as if the practice of radiotherapy would increase. Dosage was now becoming standardised and for the most part adequate doses were given. Dr. Hurdon referred to figures given by Dr. J. Lane-Claypon in her survey of the subject, published by the Ministry of Health. Over a period extending to five years after treatment the results of operation and of radium were about the same—40 per cent. of non-recurrences, whereas radium gave an additional 12 per cent. in cases which were inoperable when first seen. Unfortunately more than half of the patients presented themselves when the growth was already inoperable, usually six to nine months after symptoms had first been noticed. In the series of cases treated by the committee of the Women's Medical Federation only 15 per cent. were operable when first seen. As to technique, a modification of that used by Heyman, of Stockholm, was adopted, since on the whole his results over long periods seemed to be better than those of others. Many continental clinics used this technique, though in France and Italy that of Regaud seemed to be more favoured. It was too early yet to make any claims for the final outcome of treatment in the cases under Dr. Hurdon's observation, but the following results were of interest. 188 cases had started treatment during the period October, 1925, to April, 1928. Of these, 169 were cases of cancer of the cervix, 15 of cancer of the corpus, and four of cancer of the vagina or vulva; 70 per cent. of these cases were living in March, 1928, 30 per cent. being dead. Of the operable cases over 95 per cent. were living and free from symptoms. The immediate mortality of treatment by radium was nil, but certain complications might occur subsequently, such as fistulæ, rectal ulcer or rectal pain, tenesmus, and the passage of blood or mucus. These complications were happily rare—for example, fistulæ attributable to radium had occurred in only two cases in the series under discussion. The following up of patients was most important. Though it was very difficult to trace them, especially in London, only two had been lost sight of.

Dr. H. CHAMBERS pointed out that a final decision as to the most suitable technique could only be made after years of trial. But the work of Prof. S. Russ on experimental animals had been most helpful. He had inserted tubes of radium and then excised a piece of the tumour after varying intervals, testing the viability of the portion excised by transplantation into another animal. In this way the range of effect, which was the most important factor to be considered, could be estimated. Dr. Chambers showed diagrams of the various methods used in different clinics, explaining that the method of inserting a tube into the cervix without any other tubes in the vault of the vagina could not be adequate over a sufficient area. She explained the importance of distributing the tubes, since the range of effect did not exceed half an inch. Soft rays had low penetrating power and caused local sloughing, hence the need for screening. The ideal aimed at was the disappearance of the growth with the minimum damage to healthy tissues, and gamma rays appeared to be the most useful agent available for this purpose.

Prof. LOUISE MCILROY congratulated the Association on the first piece of organised research undertaken by medical women as a group. She commented on the fact that patients in early stages often omit to tell their doctors of the symptoms, since these may be very slight, perhaps a little hæmorrhage and no pain, even when the growth has reached the inoperable stage. For the last two years Prof. McIlroy had ceased operating on cases of cancer of the cervix, using radium instead, with what appeared so far to be excellent results. It was important to disseminate the knowledge that non-operative treatment was available since this might lead patients to seek advice earlier.

Miss G. DEARNLEY said that the improvement in general health after radiotherapy had struck her. She had removed one uterus after treatment and no trace of growth could be found even microscopically.

Miss L. MARTINDALE said that more beds were urgently required. It was often embarrassing to find room for patients to return to hospital for the requisite three doses.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Liverpool on March 16th, Dr. LEITH MURRAY, the President, in the chair. A paper on

Cystoscopy in Carcinoma of the Cervix,

based on a study of 111 cases, was read by Dr. A. A. GEMMELL (Liverpool). He described the method employed to determine clinically the operability of cases of cervical cancer, and pointed out that cystoscopy added "sight" to "touch" in estimating anterior extension. The appearances seen were described, in their order of gravity, as being: (1) bulging of the floor of the bladder; (2) circulatory changes; (3) transverse ridging; (4) œdema—(*a*) diffuse, (*b*) bullous; (5) desquamation; and (6) malignant invasion—(*a*) ulcerative, (*b*) hypertrophic. There were also other and rarer changes. Dr. Gemmell insisted that the lesions seen were *not* pathognomonic of carcinoma of the cervix, but were nevertheless important when seen just behind the trigone. All his findings had been checked by pathological examination of the growths. In a few instances in which it had been possible to do a second cystoscopy, the order of severity of the appearances mentioned had been confirmed. The bladder symptoms of the patients had been investigated, and it had been shown that in both operable and inoperable groups approximately 50 per cent. of patients had no urinary symptoms, whilst 30 per cent. complained of frequency. It seemed, therefore, that bladder symptoms were no guide to the degree of

bladder involvement. The appearances of the bladder in operable cases (39) and inoperable cases (72) were recounted. Five cases, clinically classed as operable but by cystoscopy classed as inoperable, were found on further investigation to be inoperable. Of seven borderline cases, five were submitted to operation only because the cystoscopic findings were favourable, and their after-histories had justified the interference. It was concluded that early transverse ridging was the sign which denoted the limit of operability. The appearances of the ureteric orifices were no guide to the difficulties likely to be encountered in their dissection, and catheterisation of the ureters was advised for this purpose. In order to determine whether the bladder was adherent to the cervix, Dr. Gemmell recommended the following manœuvre. Before the introduction of the cystoscope, a volsellum forceps is attached to the cervix. While the retrotrigone is being inspected, traction is put on these forceps. When there is no attachment between the cervix and the bladder, the former is seen to slide behind the latter; where attachment exists the bladder wrinkles up. He concluded by discussing the pathology underlying the abnormal signs in the bladder, and quoted figures suggesting a connexion between the cystoscopic appearances and prognosis.

The PRESIDENT said that he knew from personal experience the value of cystoscopic examination as an aid to judging operability in carcinoma of the cervix.

Mr. ROBERT KENNON (Liverpool) congratulated Dr. Gemmell on his intensive cystoscopic study of carcinoma of the cervix, and especially on his interesting observation that with the cystoscope early adhesion to the bladder could be detected by following the movements of the cervix, reacting to the drag on a volsellum forceps. A sign so simple should be of wide application and value. Transverse ridging and bullous œdema, if in the retrotrigonal area of the bladder, had a grave significance.

Prof. MILES PHILLIPS (Sheffield) said that he had found the cystoscope very useful in these cases, and agreed that the ridge and furrow appearance was a sign that the limits of operability had been reached.

Mr. F. A. G. JEANS (Liverpool) agreed that the appearance of the ureteric orifices was no guide to the condition of the ureters in relation to extension of the growth.

A number of cases were described.

Reports and Analytical Records.

ROBB'S NURSERY BISCUITS AND BISCUIT POWDER.

(ALEC ROBB AND CO. LTD., ATKINS-ROAD, CLAPHAM PARK, LONDON.)

THIS well-known product can be used, mixed with milk, as a food for infants from 6 or 7 months of age, and as a nourishing and sustaining food for invalids and persons of weak digestion. The powder is prepared from the biscuits, and when analysed the following results were obtained :—

	Per cent.
Moisture	5·68
Ash	0·74
Fat	6·70
Proteins	10·15
Soluble carbohydrates (including dextrins)	15·70
Insoluble carbohydrates (starch altered by baking)	60·00
Residue surviving digestive processes	1·00

The last-mentioned figure supports the claim of the makers as to the easy and complete digestibility of the biscuits, which are crisp and pleasantly flavoured. When used according to the directions given, the biscuits or powder constitute a useful and valuable foodstuff.

Reviews and Notices of Books.

PHYSICAL CONSTITUTION IN MENTAL DISEASE.

Significance of the Physical Constitution in Mental Disease. Medicine Monographs. By F. L. WERTHEIMER, Associate in Psychiatry, Phipps Psychiatric Clinic; and FLORENCE E. HESKETH, Charlton Fellow in Medicine, Johns Hopkins University. London: Baillière, Tindall and Cox; Baltimore: Williams and Wilkins Company. 1926. Pp. 87. 11*s.* 6*d.*

THIS monograph deals with the study of 65 male patients chosen at random from the Phipps Clinic and the State Hospital, and classed into four diagnostic groups, those predominantly affective (manic depressive), schizophrenic reaction types, organic reaction types, and psychopathic personalities and psychoneuroses. They were studied from two main standpoints, first by observation of various bodily features as a basis for grouping into types mainly following those of Kretschmer, and secondly, according to anthropometric methods, measurements being taken of 53 values following the technique of Martin and Hrdlicka; the attempt was then made to see whether the latter values, or indexes derived from them, could be correlated with the former, and either or both with the mental abnormality. From frequency distribution curves no indication of bimodal or trimodal frequency was found, and no morphological types were found to emerge from the anthropometric measurements. The indices commonly used are unsuitable for mental patients, whose frequent changes of weight interfere with their value. The authors advocate the use of a new index using skeletal points alone, consisting of—

$$\frac{\text{leg length} \times 10^3}{\text{Transverse chest} \times \text{sagittal chest} \times \text{trunk height}} \times 100$$

They do not, however, give exact directions for the taking of these measurements. This index is based on the idea that the relation of trunk volume to limb length may be correlated with morphological types; and it was found to correlate well with the type distribution obtained by observation, the high index values corresponding to the asthenic type and a predominantly schizophrenic mental reaction, while the low index values appear in the pyknic types and the manic depressive cases. The importance of considering age-incidence in such studies is emphasised, this being an important source of error.

The authors suggest using the terms syntropic and idiotropic for the groups of prepsychotic personalities tending to correspond with the morphological types, instead of Kretschmer's cycloid and schizoid, which unduly stress an uncertain relationship to psychosis. They point out that premature correlation of such types with endocrinology is unwise until more accurate knowledge is available. The introductory chapter on the history of the study of types is particularly valuable.

CLINICAL PATHOLOGY.

Second edition. By P. N. PANTON, M.A., M.B., Clinical Pathologist to the London Hospital and Director of the Clinical Laboratories; and J. R. MARRACK, M.A., M.D., Chemical Pathologist to the London Hospital. London: J. and A. Churchill. 1927. Pp. 459. 16*s.*

THIS volume is long overdue. Time was when Panton and Clinical Pathology were almost synonymous in the mind of the average medical student; but 15 years is a long while between editions, and in these latter days the inflow of works on the subject from the west can only have been equalled by the outflow of gold in the opposite direction. The present volume is a worthy successor to the first edition, and the association of Dr. Marrack with Dr. Panton is a recognition of the growing importance of chemica

pathology. In the preface to his original edition Dr. Panton stated "where several methods for the same object are in use, one, or at most two, are described in full: the remainder are omitted altogether." This wise principle has been followed in the present edition and for the most part with the happiest results. In the section on the examination of the cerebro-spinal fluid there would, however, seem to have been room for some test for protein between the crudity of the alcohol method and the finesse of the quantitative technique of Wu as modified by Hewitt; Pandy's test and some of the nephelometric methods, for instance, are simple and useful. No mention is made of the extreme desirability of direct matching before transfusion. In view of the difficulty of obtaining satisfactory samples of Leishman's stain the inclusion of Wright's method for staining blood films might have been found useful. These are small matters which can easily be set right. The book as a whole is admirable—clear, concise, and to the point. The sections on the indications for and the interpretations of the various procedures described are judicious, the general sanity of outlook is well shown in the question of vaccines, and the volume is sure of a wide popularity among medical students and practitioners alike.

AIDS TO OPHTHALMOLOGY.

Seventh edition. By N. BISHOP HARMAN, M.A., M.B. Cantab., F.R.C.S. Eng., Senior Ophthalmic Surgeon, West London Hospital. London: Baillière, Tindall and Cox. 1928. With 164 illustrations. Pp. 236. 3*s.* 6*d.*

THIS excellent little book will be very hard to supersede. Though small in size and cheap, it is a reliable vade mecum for the student and contains all that a practitioner who does not profess to have specialised in eyes, or to be an authority on the fundus, is likely to want. Even if he possesses a larger work, it will be well worth his while to purchase this one where, besides a good account of the ordinary diseases and of the art of refraction, he will find some practical hints which he is not likely to find elsewhere—e.g., how to avoid a corneal abrasion when removing foreign bodies, and how to preserve watery solutions of alkaloids used in eye-work. There are two new chapters in this edition, one on eye-signs of body disease, and the other on the blind. The chapter on glaucoma is enlarged, but on a subject over which there is still considerable controversy the necessity of being somewhat dogmatic in a book of this size is plain. One of its great merits is that it can easily be carried in the pocket. It would be a pity to enlarge it materially, but one addition would be welcome, and that is a list of the few drugs which the author habitually uses, with their appropriate strengths.

GIDEON ALGERNON MANTELL,

Surgeon and Geologist. By SIDNEY SPOKES, M.R.C.S. London: John Bale, Sons, and Danielsson. 1927. Pp. 263. 12*s.* 6*d.*

THIS is the biography of a doctor whose bent lay in geology, especially that of the Sussex Downs. The form does not make for easy reading—it is a tissue of extracts from letters, papers, and other documents, knitted together with explanation and comment—but when the reader becomes accustomed to it he makes contact with the tragedy of a disappointed Brighton practitioner who never had quite the courage of his aspirations, who permitted circumstance to cripple him figuratively in his creative work and literally in his spine, and who died after years of frustration and suffering, leaving fragments of brilliant work where there might have been a coherent whole. Lovers of the South Downs will be able to find illuminating side-lights on the life of these hills a hundred years ago, and the geologist will discover much to interest him.

THE POLYNUCLEAR COUNT.

By W. E. COOKE, M.D., Director of the Pathological Department, Royal Infirmary, Wigan; and ERIC PONDER, M.D., D.Sc., Associate Professor of General Physiology, New York University. London: Charles Griffin and Co., Ltd., 1927. Pp. 79. 6*s.*

THIS little book contains what is probably the best exposition of the rationale, technique, and interpretation of the Arneth count as yet made available in the English language. Though some might contest the statement, probably most of those in this country engaged in the study of the blood would agree that the Arneth count has not yet established its place in clinical hæmatology. While they make no undue claims for the procedure, the authors of the present work are of the opinion that if properly carried out it is capable of affording valuable information, in particular in regard to the activity or otherwise of foci of chronic or subacute sepsis; and they make out an excellent case for their thesis. So far the chronic infection in which the Arneth count has mostly been used is pulmonary tuberculosis. While showing plainly the help which the count can afford in following the course of a tuberculous infection the authors also draw attention to its uses in other directions—e.g., the presence of septic foci in teeth or tonsils. A suspicious tonsil or tooth can in their opinion be condemned if the count shows a shift to the left (implying a preponderance of youthful polynuclear cells), but should on no account be condemned if such a shift is wanting. That the Arneth count has failed to take an important place in medicine is partly to be attributed to faulty technique. The authors describe a simple and effective technique within the reach of everyone possessed of a bottle of Giemsa stain and a microscope. The book is produced in the first-rate style of a technical manual.

SANITARY LAW AND PRACTICE.

Sixth edition. By W. ROBERTSON, M.D., F.R.C.P. Ed., D.P.H., Medical Officer of Health, Edinburgh; and C. PORTER, B.Sc., M.D., M.R.C.P. Ed., Barrister-at-Law, Medical Officer of Health, St. Marylebone. London: Sanitary Publishing Co., Ltd. 1928. Pp. 815. 21*s.*

THIS book first saw the light in 1904. It has long been a favourite with candidates for the public health diploma, and generations of students brought up on it have grown into well-informed officers. Its chief value lies in the arrangement by which under each subject heading—e.g., food, dairies, infectious diseases—precise information is given as to what is done by the official to carry out the duties placed upon him, and to make use of the powers he possesses. The writers claim to condense the legislation; they do more than this, they translate the legal technology into intelligible English. Perhaps the principle could be carried further, and the legislation on disinfection, for instance, taken out of the general section on infectious diseases and placed conveniently in front of the text dealing with the practice of disinfection. The book is probably not intended by its authors to give the student a conception of the relative importance of the several branches of public health work. Thanks to the work of an earlier generation of health officers, environmental hygiene has improved out of recognition in the matter of water-supplies and sewage systems, and the book contains no hint that venereal diseases present problems more urgent than do (say) canal boats. No mention is made of the welfare work in factories of which the future will have much to say, and the title "social hygiene" does not appear. But apart from what may be an intentional narrowing of scope and a certain greyness of diction, illuminated at times by a graphic sentence, it would be difficult to select for praise any special section where all are so good. The section on vital statistics,

however, stands out in its treatment of a difficult subject in a manner at once practical, comprehensive, and intelligible; and there is a masterly analysis of the complex sanitary legislation embodied in the London County Council (General Powers) Acts, 1893–1927.

We may congratulate the authors on the feat they have performed in digesting the ever-growing volume of public health legislation and in affording material for comparative study of English, Welsh, Scottish, and Irish sanitary law. Medical officers of health will find the book extremely valuable for reference.

PHARMACOGNOSY AND MATERIA MEDICA.

By HOMER C. WASHBURN, Ph.C., B.S., Professor of Pharmacy and Dean of the College of Pharmacy, University of Colorado; and WALTER H. BLOME, Ph.C., M.S., Director Scientific Laboratories, Frederick Stearns and Company, Detroit. New York: John Wiley and Sons. 1927. Pp. 585. 25*s*.

PHARMACOGNOSY, in the traditional sense, is a subject which, if not dying, is at least fighting a retreating battle. The laboratory chemist and the maker of synthetic drugs have largely replaced the hunter of herbs. But what is left of the vegetable world in medicine needs the careful description which it gets in the book before us. Written in the first instance for practical pharmacists, the book is not devoid of interest for the practitioner of medicine. The authors decry the spending of much time on microscopical structure of drugs, and adhere to the old-time arrangement according to the natural order of the plants from which the drugs are derived. In two of the aims the authors have succeeded well: (1) to leave in the mind of the student a clear conception of important features and facts concerning plant and animal drugs; and (2) to make a work of safe and ready reference for the busy pharmacist, whether he be retailer, wholesaler, or manufacturer. Great care is taken to make pronunciation clear by symbols which at times place the accent unfamiliarly to English readers. Derivation, too, is accurately given, although we incline to doubt the origin of poplar (pōpulus) from the "arbor pōpuli" planted along the public ways of Rome. The illustrations do not quite rise to the level of the text.

STANDARD METHODS.

By AUGUSTUS B. WADSWORTH, M.D. London: Baillière, Tindall and Cox. 1927. Pp. 704. 34*s*.

THIS book is a complete exposition of the methods in use in the laboratories under the administration of the State Department of Health in New York. It differs from the usual manuals of laboratory method in the omission of staining procedures, though formulæ are given; the reduction to a minimum of general instruction in elementary technique; and the full and detailed description of methods—e.g., serum production—which are absent from most manuals. A good deal of the material presented is extremely novel in a publication of the sort. We would instance the chapters upon administration and on the methods used in the research, publications and library department. Whilst no administrator is likely slavishly to follow the methods set forth, their perusal will nevertheless be found to be stimulating and suggestive. It may be a matter of amazement to any who are inclined to look upon the laboratory as something of a new-fangled luxury and not an essential adjunct to medicine to realise that the very progressive institute from which this volume comes employs, besides the director and assistant director, a staff of 5 bacteriologists, 1 pathologist, 5 chemists, 1 veterinarian, 15 assistant bacteriologists, 2 assistant serologists, 2 assistant pathologists, 9 assistant chemists, 12 laboratory assistants, 4 laboratory apprentices, 52 technical assistants and helpers.

We can thoroughly recommend this volume to bacteriologists and directors of pathological institutes as a mine of useful information. To any who are called upon to design laboratories it will be a veritable godsend.

TREATMENT BY MANIPULATION.

Being the second edition of "Manipulative Surgery." By A. G. TIMBRELL FISHER, M.C., F.R.C.S., Surgeon to the Seamen's (Dreadnought) Hospital, Greenwich. London: H. K. Lewis and Co., Ltd. 1928. Pp. 200 9*s*.

THE second edition of Mr. Fisher's book appears under a new title, but differs from the first chiefly in the addition of some case-histories and considerable enlargement of the sections dealing with osteopathy, tennis-elbow, chronic arthritis, and lesions of the sacro-iliac joint. All these subjects are attracting a good deal of attention from orthopædic and general surgeons at this time, and they demand the space devoted to them. As regards osteopathy Mr. Fisher is right to point out the evil results, in some cases, of manipulations carried out by ignorant quacks, who are incapable of making a preliminary diagnosis. Tennis-elbow is a subject that needs all the light that can be thrown upon it, for its pathology is by no means satisfactorily explored or established, and its unsuccessful treatment is often made a reproach to surgery. The pendulum has swung away from the teaching of Hilton, and other surgeons besides Mr. Fisher are getting gratifying results from the treatment by limited movement of inflamed joints, even in such cases as tuberculous disease of the hip in young persons. As to lesions of the sacro-iliac joint, the experience and consequently the views of surgeons differ, but it appears that surgical opinion is coming round to the view that inflammatory and traumatic lesions of this joint are not so rare nor so dangerous as used to be thought. This edition will no doubt be even more welcome to the profession than its predecessor.

SCHOOL COURSE IN HYGIENE.

By ROBERT A. LYSTER, M.D., Ch.B., B.Sc. Lond., D.P.H., County Medical Officer of Health, Hampshire; Lecturer in State Medicine at St. Bartholomew's Hospital, London. London: W. B. Clive, University Tutorial Press, Ltd. 1927. Pp. 234. 3*s*. 6*d*.

THIS little book is an adaptation for school use of the author's "First Course in Hygiene" (now in its seventh edition), from which the more advanced portions have been eliminated, but the distinctive features retained. Human anatomy and physiology are presented along with hygiene and public health as associated and dependent parts of a whole, and practical work is introduced where suitable at the ends of chapters, the experiments being designed to illustrate essential principles. For the teacher's use a number of test questions on each chapter is included. The text is an admirable presentation of what may be regarded as the older type of instruction in hygiene; the information given is solid, the writing in places remarkable for its clarity, and the facts, as a rule, well selected. But whereas much of the text on hygiene might be read with interest by the average child, some of the physiology and anatomy is further removed from the facts of everyday life and experience, and it is difficult to avoid the conclusion that the book does not wholly carry out the aims of the recent "Handbook of Suggestions on Health Education," which contemplates teaching in the form of lectures or talks by the teacher. Should the teacher not be interested in the subject the class reading of Dr. Lyster's book would be a useful alternative, while for individual study by a young child the book is good, although it could be better. Practically all the illustrations are beyond cavil; a few are exceptionally good.

THE LANCET.

LONDON: SATURDAY, APRIL 14, 1928.

STEREOSCOPIC RADIOGRAPHY.

THE correct explanation of the way in which a solid is seen in relief was given as long ago as 1833 by Sir CHARLES WHEATSTONE, although he was contradicted by Sir DAVID BREWSTER and other orthodox physicists of his time. WHEATSTONE induced FOX TALBOT, one of the inventors of photography, to use the new art for taking stereoscopic pictures, with results which are now well known. When the discovery of X rays, in 1895, made it possible to see shadows of the various internal organs of the body, it was soon realised that the radiographic pictures so obtained often failed, because of their lack of relief, to give just the information required of them; and this led radiologists to apply the laws of stereoscopy to X ray photography. The subject has recently been developed by Dr. WILLIAM COTTON in a brochure entitled "Perspective in Relation to X-ray Interpretation." It may not be out of place to restate here some of the conditions essential to obtaining an X ray picture in relief. First of all: binocular vision is necessary for stereoscopic effect. The view of any solid body as seen with the right eye is slightly different from that seen with the left, and it is the combination of these pictures which results in a view showing relief. In photographic stereoscopy, two cameras placed side by side replace the observer's eyes and photographs obtained simultaneously in this way are combined subsequently to give a view of the subject in relief. Correct stereoscopic relief is obtained if the right and left eyes of the observer look only at the views appropriate to them. In radiography, the two slightly differing pictures are usually obtained by exposing two X ray films in succession at the same place relative to the subject and moving the X ray tube between the exposures. The fact that the two views are not simultaneous introduces a grave drawback where the stereoscopy of a moving organ is required.

Mention has recently been made in our columns of an orthostereoscopic apparatus designed by Mr. F. E. BORNHARDT, in which the problem of simultaneity has been solved by utilising every recent device in the manufacture of tubes and screens. Robust hot cathode X ray tubes, efficiently water-cooled to withstand heavy electric discharges, are now made so small that two of them can be placed close enough together for stereoscopic reproduction, thus obviating the shifting of the tube which was necessary with the earlier and larger type. The two tubes are connected to the same alternating current transformer, and current is allowed to flow first through one tube and then, on its reversal, through the other. The rays from both fall on the same fluorescent screen. The alternating current reverses 100 times each second, and during this period the same number of views of the subject will fall on the screen, consecutive pictures forming a stereoscopic pair. To obtain a stereoscopic effect it is necessary to ensure that the observer's right and left eyes see only those views on the screen which are appropriate to them. The fluorescent screen is therefore viewed through circular diaphragms carrying apertures and revolving in synchronism with the discharges through the X ray tubes. The diaphragm before the observer's right eye only allows a view of the screen during those periods when the X ray tube on his left hand side is illuminated; between these periods the left eye sees the screen picture made by X ray tube on the observer's right hand. The rapidity with which the views repeat themselves gives to each eye a continuous impression, that received by the right eye combining with the slightly different view falling on the left one to give stereoscopic relief.

The new instrument appears to mark a definite advance in radiography. The principle of direct stereoscopic screening is not new in itself; an apparatus was evolved some years ago which made use of a gas-filled tube with two anticathodes contained in the one bulb, but connected to two coils and a special commutator; the viewing shutters were operated by hand, but the smoothness and rapidity with which the different pictures follow each other in the present model has removed one of the main defects of the older methods. It must be realised, however, that success will depend upon the efficiency of the fluorescent screen and its freedom from phosphorescence. The orthostereoscope has already been installed in some continental clinics, and we shall await with interest the results obtained with it in this country.

THE RETICULO-ENDOTHELIAL SYSTEM.

DURING the last 10 or 15 years the term reticulo-endothelial system has become increasingly popular and is now firmly established. It embodies a conception which is by no means new though it has only been defined with any degree of rigidity within comparatively recent years. In the earliest days of histology the presence of mononuclear cells was recognised in the connective tissue in various parts of the body. For the most part they are few in number and apparently unimportant but in certain conditions, particularly in some forms of inflammation, they appear in enormous numbers and in a bewildering variety of form. The origin and differentiation of these elements has been closely studied by numerous observers. Each new entrant into the field has enriched the literature with at least one new name, and the whole subject has become as complex and difficult as could possibly be imagined. How many types of mononuclear cells occur in the tissues, and whether they are derived from wandering blood cells, from endothelium, or from primitive mesoblastic cells, is far from being settled, but certain facts have emerged in recent years which help to bring some semblance of order into at least a part of this subject. METCHNIKOFF was really the first to recognise that in many situations the fixed tissue cells, as distinct from the cells of the circulating blood, have remarkable powers of phagocytosis. He described a system of macrophages, widely distributed in the body, which have in common the power to phagocytose and metabolise red and white blood corpuscles. Of course, practically all the cells in the body have this function, but as ASCHOFF has pointed out, the macrophages of METCHNIKOFF differ from other cells in the intensity and frequency with which they perform it. The matter was carried a step further by RIBBERT who, using the method of vital staining, showed that after the injection of solutions of lithium carmine into the circulation the dye was found in the cells in only certain places. His work has been continued by many others and it is now

clear that there exists a type of cell, distributed irregularly in various parts, which reacts similarly to the presence of several dyes. It is possible, then, to group together in this way the reticulum cells of the spleen and lymph nodes, the cells lining the sinuses of the spleen, lymph nodes, bone-marrow and liver, and various wandering mononuclear elements, the monocytes of the spleen and the histiocytes, clasmatocytes, or leucocytoid cells of the tissues. These cells constitute the reticulo-endothelial system, and the more they are studied the clearer does it seem that they do in fact function as a definite unit. Physiologically one of their main activities seems to be concerned in the metabolism of iron—they play an important part in the phagocytosis of red blood corpuscles and in the formation of bile pigment, though the actual groups of cells concerned vary in different animals. In mammals, for example, the spleen appears to be the chief phagocytic organ, whereas in birds the spleen and bone-marrow contain comparatively few reticulo-endothelial cells, the liver being the organ in which they are congregated. And the system has other metabolic activities. In diabetes and in conditions of cholesteræmia the cells tend to store up cholesterol esters—and in Gaucher's disease, of which the obvious manifestation is splenomegaly, the phagocytes of the spleen proliferate and become enormously distended with a phosphorus-containing substance, probably a protein. In infections, again, the reticulo-endothelial system seems to have an important function in the defensive mechanism of the body—not only do its cells phagocytose invading bacteria and protozoa, but there is a good deal of evidence that they are closely concerned in the formation of antibodies. A great amount of work remains to be done in clearing up the many problems which a scrutiny of the recent work reveals. But, however it may be modified in the future, there seems little doubt that the main doctrine of the reticulo-endothelial system will remain unchallenged.

THE TREATMENT OF EMPYEMA.

THERE is still some difference of opinion on the best method of treating empyema in children, and particularly on the relative merits of open and closed drainage and the value of irrigation in promoting closure of empyema cavities. In the first of three recent papers dealing with this subject Dr. D. W. Parker[1] advocates the closed method. Under novocaine anæsthesia he makes an incision down to the intercostal muscle, which he perforates with a pair of scissors. Through this opening he introduces a 24–27 F. catheter which has been previously pushed through a hole in the middle of a 3-in. square of rubber. The rubber makes a shield 1½–2 in. from the tip of the catheter, and as soon as pus begins to flow the catheter is clamped, the skin incision is closed, and the rubber dam is fixed to the chest wall with adhesive plaster. A syringe is then attached to the catheter, the pus is aspirated, and for the first 24 hours after operation the cavity is irrigated two-hourly with 1 per cent. chlorazene, or Dakin's solution; a 30 c.cm. syringe is used for this purpose and not more than 60 c.cm. of fluid is injected without being withdrawn again. Between aspirations the catheter is attached to a tube which hangs down into a water-containing receptacle under the bed, and this tends to syphon out pus from the chest. Dr. Parker considers that irrigation is a specially important part of the treatment, because it helps to dissolve fibrinous or partly organised pleural adhesions, whilst the syphonage assists re-expansion of the lung. He claims that this method is painless and affords adequate drainage without subjecting the patient to serious shock. An account is given of 18 cases in children under 10 years treated on these lines with only one death. Two of the children were under one year old, six between 1 and 2, and four between 2 and 3. As a rule the tube was left in for 15–20 days. Further evidence in favour of early closed drainage has been collected from many sources by Dr. J. M. Hayes,[2] who thinks it desirable both in children and adults. Early open drainage, he says, causes pneumothorax, disturbs the mediastinal structures, lessens the vital capacity of the lungs, and impedes re-expansion. Closed drainage, besides avoiding these risks, is more comfortable for the patient. The method which he recommends is as follows: A 22 F. catheter is introduced into the lowest part of the cavity by means of a trocar and cannula, and is fixed by four strips of adhesive plaster, two extending vertically and two horizontally, so that the opening about the tube is tightly closed and entrance of air is prevented. Irrigation with Dakin's solution is then done with advantage every two hours during the first four days until the cavity has considerably decreased in size. After this Dr. Hayes considers there is no harm in open drainage by rib resection over the cavity. In a third paper Dr. C. E. Farr and Dr. M. L. Levine[3] review 371 cases of empyema in children under 10 years old. The most striking fact which emerges from their paper is the importance of age in relation to incidence and mortality, the curves of both these factors reaching their apex in the first year and then falling steadily until the age of 9. They consider that of all factors in prognosis age is the most important. Next to this is the kind of infection and the virulence of the organism, which may vary from year to year. In 134 cases of this series in which the organism was determined 73 were pneumococcal and 23 streptococcal, each with a mortality of 26 per cent.; 6 were staphylococcal, with a mortality of 66 per cent.; 12 were mixed infections and 20 were sterile, the mortality in the two last groups being 42 and 30 per cent. respectively. Pneumococcal infections were comparatively rare (22 per cent.) during the first year, when mortality is high, compared with later years (60 per cent.). As a possible aid to prognosis leucocyte and differential counts were done in 104 cases, but the results were very variable and no prognostic deductions of value could be made from them. All cases were first treated by aspiration, both for diagnosis and drainage. In those which occurred during acute pneumonia, aspiration was continued until the condition of the patient favoured open drainage. Intercostal incision or rib resection, followed by open drainage, was used ultimately in all but three, whose end would only have been hastened by operation. Closed drainage was not employed at all. Farr and Levine consider that death from empyema in children is almost always due to the debilitating effect of previous illness or to other complications, which include pneumonia, rather than to the empyema itself. They think that the various methods of incision and drainage have very little influence on prognosis compared with other factors, such as the age and general resistance of the patient and the virulence of the infection.

In surveying this expression of recent American opinion, we should feel for our part that the decision

[1] Boston Med. and Surg. Jour., 1927, cxcvii., 653.

[2] Minnesota Medicine, 1928, xi., 16.

[3] Surgery, Gynecology, and Obstetrics, 1928, xlvi., 79.

to employ an open or closed method of drainage is not of such moment to the patient as the choice of the most favourable time to perform the operation. Whether the patient is to be left with a large cavity which will not heal without further surgical help, whether, in fact, he is to become a chronic invalid, depends scarcely at all upon whether an open or closed method of drainage has been used, but upon the presence or absence of adhesions round the periphery of the empyema which are strong enough to prevent the lung from collapsing when the cavity is opened. Aspiration should be employed until the surgeon is reasonably sure that this state of affairs exists. The removal of thick pus with a needle is usually a sign that it is safe to open the cavity. When only turbid fluid is withdrawn operation had better be postponed. In this stage also the sudden collapse of the lung which the operation would bring about has other dangers for the patient beyond that of leaving him with a chronic empyema cavity; it may suddenly flood the circulation with a dose of toxin with which he is unable to deal. Early operation in empyema is immediately risky and may be the cause of serious later trouble. Many surgeons will agree with Farr and Levine that the method of drainage has very little significance upon prognosis. The various closed methods of drainage have all been devised with the idea of making this discharge of pus easy while the ingress of air into the chest during inspiration should be hindered. As a rule, there is scarcely any advantage to be gained by using them; sometimes indeed they impede, to some extent, the exit of pus. A simple moderately sized drainage-tube cut almost level with the skin round which the tissues are snugly sutured and covered with a thick dressing is very satisfactory. With coughing and other expiratory efforts pus can be freely expelled, but during expiration the dressing is sucked tightly against the open end of the tube, thereby occluding it. Particularly when the gauze is soaked with discharged pus does this valvular mechanism come into play. The simplest method seems here the best. Whether for drainage an intercostal incision should be made or a piece of rib removed does not seem to be very material; it should be remembered, however, that when aspiration has shown pneumococci alone to be present, it will sometimes be possible to avoid any operation whatsover. Repeated aspiration may suffice to bring the case to a successful conclusion.

INTERNATIONAL CANCER CONVENTION.

WE announced some weeks ago that the British Empire Cancer Campaign was to hold an international convention in London in July, and we are now able to give a provisional account of the programme. On Monday, July 16th, the delegates will be received by the President, Sir John Bland-Sutton; the following day will be given up to general discussions on the relative value of surgery and radiation in the treatment of cancer of the cervix, rectum, buccal cavity and breast, and on the ætiology of cancer; whilst Wednesday, the 18th, will be devoted to sectional discussions and a reception by the Duke of York. The subjects to be considered by the various sections include the biological effects of radium and X rays; occupational cancer; the relations between clinical malignancy, histological characters and response to treatment; diagnostic methods; the geographical and racial prevalence of cancer; and the public action that should be taken to control the disease. The section of surgery will have a session on cancer of the stomach, and there will be a general discussion of chemotherapeutic methods, with special reference to lead, by the Convention as a whole. Those who wish to contribute to the discussions should communicate with Mr. Cecil Rowntree, chairman of the executive subcommittee, at 9, Upper Brook-street, London, W. 1. It is hoped to arrange for operations and demonstrations at various centres every afternoon during the meeting.

Annotations.

"Ne quid nimis."

THE CAUSATION OF GLAUCOMA.

GLAUCOMA is essentially an increase in the intra-ocular fluid pressure, greater than the inextensible outer coat of the eyeball is able to sustain without involving serious injury to the visual mechanism which it encloses. The fluid content of the eyeball is in either constant or intermittent flux, the ingress depending either, as Treacher Collins first taught, on the secretory activity of the ciliary body, or, as W. E. Duke-Elder maintains,[1] on the osmotic interchange of fluid through the capillary walls, whilst the egress depends, apart from this same osmotic interchange, on the efficiency of the drainage system. In normal eyes this is so perfect that any extra influx of fluid into the eyeball is at once compensated for by an extra outflow of an equivalent amount. It was at one time supposed that the cause of glaucomatous rise of tension is to be found in an increased influx of fluid, and recently this idea has been revived by E. P. Fortin.[2] On the other hand, the view till lately almost universally held is that the cause of high tension is an interference with the drainage system by the partial or complete closure of the angle of the anterior chamber, rendering it difficult for the aqueous to have access to Schlemm's canal. Nevertheless, Duke-Elder, in the work already referred to, inclines to the opinion that obstruction to the exit of fluid is a secondary or adjuvant factor in the ætiology of the disease. In chronic glaucoma adhesions of the periphery of the iris to the back of the cornea have been demonstrated and it is generally believed that such adhesions are facilitated by a large crystalline lens, a relatively small cornea, a swollen ciliary body, and, generally speaking, by anything which increases the pressure from behind the iris, causing the anterior chamber to be shallow. It is in these cases that the trephining operation is most likely to be successful. In glaucoma secondary to iritis or to some other primary cause the matter is not so simple. We must attack the primary condition. There are yet other cases which may show a glaucomatous cupping of the disc and a progressive contraction of the visual field without a shallow chamber and without any demonstrable rise of tension. Long ago Schnabel called these cases "cavernous atrophy of the optic nerve." Others have observed similar cases of late years, and it is difficult to understand how a trephining operation could do them any good. But borderland cases also occur in which periods of raised tension may be few and far between but do occur. We shall have to recognise that the term "glaucoma" is a wide one covering cases of varying pathology and possibly requiring varying treatment. Meantime, with regard to the great majority of cases, the weight of opinion among ophthalmic surgeons in this country will coincide with the views put forward by Mr. Leighton Davis in the article which appeared in our columns last week. It is well to remember, however, that though the trephining operation is an excellent one it can scarcely be deemed perfect. No operation in which the failures amount to as many as 9 per cent. can be considered as such, and no ophthalmic surgeon can undertake an operation for glaucoma without a certain amount of anxiety as to the result. In these circumstances, and in view of the number of cases in which any operative treatment is for one reason and another impracticable, we do not think that the importance of treatment by eserine should be minimised. In some cases it is capable of preventing the vision from deteriorating for years; though this may be exceptional, and though the practice of

[1] Recent Advances in Ophthalmology (see THE LANCET, 1927, ii., 922).

[2] Semana Médical, 1927, ii., 663.

relying upon it in cases in which it fails to reduce the tension to normal or to prevent a progressive contraction of the field can only be condemned, yet there are few cases of glaucoma in which its use as a temporary expedient is not called for. The pathology of the disease is still a matter of debate, and it would be a mistake at the present time to be dogmatic about it.

THE ÆTIOLOGY OF ALCOHOLISM.

In spite of a steadily decreasing consumption of alcohol in this country, of which there is further evidence in the figures for last year just published by the United Kingdom Alliance, it is arguable that from the national standpoint the drink problem is more serious to-day than it was 15 years ago. A country which is working on a reduced margin of industrial strength can less easily afford the inefficiency for which alcoholism is partly responsible. It may be admitted that love of sport and the open air, together with easier relations between the sexes, exerts an influence against intemperate drinking, and that "ordinary people" in this country are becoming less and less tolerant of drunkenness. But there remains a large class of people whose alcoholism calls for treatment, and it is important that the causes of their failing should receive the most careful study. The problem is one primarily for psychologists and was discussed at a meeting of the Section of Psychiatry of the Royal Society of Medicine and the Medical Section of the British Psychological Society, reported on p. 704 of THE LANCET last week.

As Dr. Bernard Hart remarked in his opening paper, the question why men take alcohol to excess is really identical with the question why they take it at all, and to this various answers have been given. One of the most obviously acceptable is that put forward by Dr. Crichton Miller, who said that alcohol was taken to modify the feeling-tone, whether this resulted from bodily or emotional experience. The two groups into which Kretschmer divides chronic drinkers are fairly well recognised by laymen as well as doctors: the type which drinks for social reasons and the type which drinks to get drunk; the pyknic cyclothymic jovial type and the schizoid, difficult and nervous type to whom alcohol is a drug. Naturally, these two groups have no hard-and-fast line between them, and many persons undoubtedly gravitate from the first to the second, but from a psychological point of view the distinction may be important. Granted that men take alcohol to ease the pressure of life on their minds and bodies, the question arises why they sometimes fall into alcoholism. Dr. J. A. Hadfield suggested that alcoholics were persons who found the responsibilities of life too much for them and used alcohol as a means of evasion. This is probably true for most drunkards, but not everyone would agree that all of them are emotionally immature in exactly the way he suggested—that they had never felt the confidence and sense of protection that every child ought to feel, and that they suffer from a chronic fear of life from which they seek to escape. Support may, however, be found for Dr. Hadfield's view in a recent and helpful survey of the field by Dr. Ernest Snowden,[1] who cites the case of a man whose mother had brought up her family to avoid showing affection. This unsound psychological training led to mental conflict when he married, and he used alcohol as a means of removing the inhibitions which prevented him from feeling marital affection. A realisation of the part which this kind of conflict may play in driving persons of a certain type to drink will help towards an understanding of the apparent obscurities of the psycho-analytical point of view. This was expounded by Dr. E. Glover, who dealt with the second or schizophrenic type of Kretschmer very thoroughly from the Freudian reductive standpoint. The Freudian sees in the confirmed drunkard a person who is attempting to extricate himself from an impasse. He takes flight from environmental reality into phantasy liberated by the dulling of the higher centres. This phantasy corresponds to definite layers of psychical development, which in the normal person are buried deep or assimilated into his adult personality, but which come into their own when the primitive impulses are released and dictate conduct appropriate to various stages of childhood. The interest of the Freudian view is its insistence on internal, instinctual frustrations as the real cause of alcoholism, and its relegation of social, habitual, and economic factors to the position of accessories after the fact. The man is supposed to find in drink a substitute for enjoyment experienced through the mouth, "oral erotism," the libido satisfaction of a baby at the breast. He has regressed to this stage of sexual development, with the result that his emotional consciousness is flooded with "castration anxiety," the protest of an inner insufficiency or impotence, or of a thwarted instinct towards self-expression. According to the psycho-analysts it is to drown castration anxiety, to short-circuit sex, that people drink to excess. Something like this may be true of the second class of drunkards; whether it is true of the first is more doubtful. It is not impertinent to suggest that the analyst must see very many more of the schizophrenic class in his consulting-room than he does of the sociable class, whose excesses exact more material penalties and who are less accessible to analysis when their breakdown is mental. As Dr. Hart pointed out, a number of working men take drink simply from a craving induced by habit, with no urge towards a refuge from reality other than the need to relax after a hard day, whilst some investigators maintain that a normal man may become an alcoholic quite fortuitously. On the other hand, Dr. W. H. Stoddart cited cases in which the need for alcohol was felt imperatively before alcohol had ever been taken. Dr. Crichton Miller gives low blood pressure as a frequent predisponent towards drunkenness, a condition by no means peculiar to the repressive or schizophrenic temperament.

The chief application of ætiological knowledge lies in prophylaxis. Dr. E. Mapother was optimistic enough to hope, in the light of the great reaction against social drinking through which this country has been passing for several decades, that alcoholism in a hundred years' time would be chiefly of interest to historians. Nothing in the discussion supported the view that alcohol itself is worthy of abolition. The consummation most Englishmen desire is that the nation should be educated in its wise use, and towards this the most important contribution is likely to be made by those responsible for education, including those who specialise in the psychological training of children, and those who, like Dr. Snowden, approach the subject from the psychological angle. If the child is enabled to face life courageously, the adult will not seek escape from it in alcoholism, or any other neurosis.

HEALTH EDUCATION.

Most people agree that public health can be improved by instructing the community in what are called the simple laws of hygiene; the difficulty is to determine how this instruction should be given. In schools it is possible to inculcate useful habits and information without much difficulty, and a certain amount is being done in this way; but the adult, whose present health is of immediate importance, is hard to approach. Among organisations for the purpose the Industrial Health Education Society has been especially happy, perhaps, in getting together the right sort of audience and obtaining an interested hearing. From the latest annual report,[1] which has just appeared, we learn how those employed in this or that industry—coal-miners, cotton operatives, bakers, tinplate manufacturers, woodworkers, and builders—have been assembled to hear talks from

[1] Annual Report for 1927 of the Industrial Health Education Society, 84, Kingsway, London, W.C.

experts and to discuss with them the risks to health peculiar to their everyday work. Thus the personal interest is aroused, as anyone must recognise who has been present at some village institute in a mining area and has heard discussions on miners' nystagmus and pithead baths, or in a Lancashire hall when mule-spinners' cancer has been debated. The society began its work in Scotland, but during 1927 its headquarters were moved to London and its activities were spread over the south and the west. The demand for lectures seems to be already greater than can be supplied from the society's funds. Hitherto, through contributions made from the Miners' Welfare Fund, the coal-mining community has been able to command most attention. But workers in other industries are realising that health is an inheritance requiring to be guarded against sickness and disease incidental to specific occupations. Though the society doubtless owes part of its success to the fact that teaching on occupational risks can be fairly clear-cut and dogmatic as compared with instruction about health in general, a special tribute is due to the competence and energy with which the work is being carried out.

BORAX AS A MOSQUITO LARVICIDE.

IN warm climates, when water is stored for purposes other than drinking, regular oiling of the surface is usually needed to keep it free from mosquito larvæ. This is an expense and, when the cost is minimised by employment of cheap (and generally unreliable) labour, an anxiety to those responsible for public health. R. Matheson and E. H. Hinman [1] have found that the addition to such water of commercial borax in the proportion of 1·5 g. to the litre, or about an ounce in six gallons, forms an efficient larvicidal solution, since young larvæ placed in it seem invariably to die. In the same way, although culex egg masses appeared at intervals in those experimental pails containing borax which were left uncovered, the larvæ which hatched never reached the second instar. Inasmuch as time and evaporation leave borax unchanged, the larvicidal effect remained as great at the end as it had been at the beginning of the six weeks' experimental period described in the paper, water having been added as required to make good the loss by evaporation. The original cost is small and there seems no reason why renewal of the solution should be required for many months. The explanation of the larvicidal character of borax does not seem to lie in its reaction. The pH of the solution in the pails did indeed stand at 9 or over, but when boric acid was used the hydrogen-ion content was indicated as 7 or less and yet the fluid was fully larvicidal. The effect must accordingly be attributed to the boron. It is hoped during the coming season to test the solution on suitable natural pools.

THE WASHINGTON HOURS CONVENTION.

WHEN the House of Commons discussed the Washington Hours Convention during the past session, the debate proceeded mainly upon party lines and the results were negative. The Convention, the terms of which were scarcely mentioned, has for its main purpose the adoption of the eight-hours day or the 48-hours week in countries where that standard has not already been attained. The British Government has refused to ratify the Convention; its spokesmen have described the document as ambiguous and unworkable, the result of a series of compromises; they have declared that it requires revision and they have argued in favour of awaiting the date (in three years' time) when it must in any case be revised. They point out that ratification of the draft Convention involves an international obligation which can be enforced at The Hague International Court by all the sanctions provided by the Treaty of Peace; they add that ratification would imperil the existing agreements which have been reached in this country whereby hundreds of thousands of workers have the prospect of employment in conditions of industrial peace. In criticising the Government, Mr. Thomas Shaw could say with considerable conviction that Great Britain, in setting her signature to the Treaty of Peace, accepted certain principles for the betterment of the lives of the workers, but had made no attempt to carry out her agreements in that respect. We ought not, he said, to allow our labour legislation, particularly for women and young persons, to sink below the level of European countries which we have hitherto regarded as somewhat backward in industrial development. The ratification of the Convention will now presumably be suspended indefinitely unless a strong public demand for it should arise. Probably public opinion in Great Britain inclines to the view that our labour questions are intricate enough already without importing international problems, that our labour legislation compares favourably with that of other countries, and that our traditions of administering justice make the enforcement of moderate laws a better thing than the adoption of rigid and high-sounding principles which are imperfectly observed. Many people, too, are resentful of the apparent surrender of legislative independence involved if Parliament at Westminster is expected to give effect without modification to draft Conventions signed in foreign countries by persons of whom the average citizen here knows little. The controversy over the Lead Paint (Protection against Poisoning) Act of 1926 was not without significance. Nevertheless, those who uphold the importance of a British Parliament in relation to legislation as to British industrial conditions would be in a far stronger position if that Parliament would fulfil its promises, made so long ago, for the revision of the Factory and Workshop Act.

[1] Amer. Jour. of Hygiene, March, 1928, p. 293.

SPLENOMEGALY ASSOCIATED WITH ASPERGILLOSIS.

UNDER the name of splenomegalie primitive aspergillaire Drs. Emil-Weil, Chevalier, Grégoire, and Flandrin in the current issue of *Le Sang* draw attention to a form of splenomegaly associated with the presence of fungi in that organ. The condition does not appear to have been recognised in this country, though it has attracted some attention in France. The essential lesion is enlargement of the spleen, though in the later stages patients may show cirrhosis of the liver, ascites, and a severe degree of anæmia. The authors point out that attention is in many cases first directed to the condition by the occurrence of severe hæmatemesis; in such cases a diagnosis is usually made of splenic anæmia of the type first fully described by Osler. A moderate degree of jaundice may be present and urobilin may appear in the urine.

Differential diagnosis during life or before removal of the spleen is difficult from that rather inchoate mass of syndromes passing under the name of Banti's disease. When the spleen is available for examination the presence of mycelial threads and even of such organs as ascospores serve to define the condition. So far as can be judged from the descriptions given by the authors, the mycelia show up fairly readily with the ordinary histological stains; the splenic tissue shows presence of inflammatory cells including giant cells and of areas of hæmorrhage with a fibrous tissue reaction. Much iron-containing pigment is deposited in the neighbourhood of the hæmorrhagic areas. The authors succeeded in cultivating fungi from a series of spleens examined and satisfied themselves that their cultures represented fungi present in the cultured material and not contaminations. Cultures grew but poorly on ordinary bacteriological media at 37° C., but good growths were obtained on Sabouraud's medium at room temperature. The fungus obtained on culture was identified by M. Jacques Duché as belonging to the genus Eurotium and was named *E. amstelodami*. All

attempts to infect the spleens of laboratory animals with the fungus proved unsuccessful. The resemblance of the histological appearances of the spleen in this condition of splenic aspergillosis to that described by Gamna [1] under the name of siderotic splenogranulomatosis is so close as to make it highly probable that the conditions are the same. Mr. Gamna, doubtless by invitation, contributes to the same issue of *Le Sang* an account of his own findings. He admits the identity of the conditions described and the frequent, if not constant, association of the splenic changes with the presence of an aspergillum, but utters a warning against too hasty acceptance of the fungus as the causative factor. On the balance of evidence, however, it would appear that Dr. Emil-Weil and his collaborators are to be congratulated on having reduced by one the number of different conditions passing under the name of "Banti's disease."

PREVENTIVE MEDICINE IN SOVIET RUSSIA.

NEWSPAPER readers in this country do not get a very favourable impression of the capacity of the Soviet Government for State medicine, but according to the Moscow correspondent of the *Münchener Medizinische Wochenschrift* (March 9th, p. 455) the authorities are coping with overwhelming problems of public health in an earnest and practical way. This writer goes so far as to suggest that Russia is the only country in the world where the age-old doctrine of prevention is really practised wholeheartedly. It is, of course, common knowledge that under the Empire the intellectual, moral, and hygienic state of the poorer classes was extremely low; that venereal disease and epidemics raged almost unchecked, and that the infantile mortality was very high—25 per cent. according to some estimates. The Soviet Government naturally visualised the medical calling as a service to the State rather than as a means of private gain. In 1922 chairs of social hygiene were established in all the universities, and the subject was made obligatory for medical students. Chairs of experimental hygiene, and of industrial and educational medicine, have been endowed at many centres of medical education. Attached to the chair of social hygiene is a clinic for social and occupational diseases, and students attend factories and schools for instruction in their especial problems. The Government is very active in health propaganda work among the people, and at the beginning of 1926 nearly a hundred centres of instruction were in operation in the large cities of Russia and several more in the Ukraine and the other republics of the Union; these centres include a museum, a lecture-room, and a library. In addition, 300 of the chief workmen's and peasants' clubs have their own hygiene museums and exhibitions, and the smaller clubs, village halls, and schools share about 2500 travelling demonstrations. There are also 15 exhibition cars on the State railways. Antenatal clinics, baby centres, creches, forest schools, day and night sanatoriums, convalescent homes, and special clinics all disseminate information about health. Visiting nurses instruct their patients in hygiene, and chemists pack their goods in wrappers bearing slogans and health rules. Over and above these measures there is a multifarious literature of popular medicine, which includes journals, handbills, book-markers, pamphlets, coloured posters, and texts. Up to the date of this account the press of the Health Commissariat had printed no fewer than 600,000 posters in two years and a half, illustrating each subject by 40 examples, and this takes no account of the publications of local health offices. 50,000 lantern slides are issued every year; mock trials are held in public to illustrate legal points of State medicine; health films are shown continually in the picture theatres, and propaganda is broadcast by wireless. The people are described as coöperating enthusiastically, and in pursuance of the principle that health reform in industrial conditions must come from the workers themselves, most town councils have health committees which attend clinics and investigate the living and working conditions of the patients. Similar committees are constituted, it is stated, in nearly all large works and firms to supervise hygiene and welfare, and every residential area elects a health committee to look after the amenities of dwelling-houses, alignment, water-supply, ventilation, disinfection, and the like. In the country similar bodies, under the presidency of the district medical officer, see to the purity of wells and springs, and organise clinics for special services and the care of school-children. Compulsory observation and treatment of venereal and trachoma patients is enforced, and alcoholics and mentally disordered persons are subject to a legal discipline much stricter than is in force in most other countries. Desperate ills demand desperate remedies, and this intensive activity at any rate shows a determination to improve what has been a parlous state of affairs. Its progress will be of the greatest interest to medical men all over the world.

MINERS' PHTHISIS.

REPORTS from the Miners' Phthisis Bureau of South Africa have hitherto been rather belated, and an effort to get up to date by combining two years in one issue [1] marks the first report by Dr. L. G. Irvine as chairman. Otherwise there is continuity of thought and of outlook with that of Dr. Watkins-Pitchford, his predecessor. During the period covered the Act of 1925 remodelled and clarified the definitions of "ante-primary," "primary," and "secondary," as applied to stages of silicosis, and introduced some changes in procedure. The work carried out by the Medical Bureau continued to increase in volume and expert skill; in particular the technical quality of radiograms keeps improving, and the Bureau rely more than ever on them for exhibiting the earliest detectable specific physical signs of silicosis. The most definite indication of good results following the stern fight which is being waged against miners' phthisis is to be found in the increasing average age of working miners; in 1917–18 the proportion of miners 30 years of age and over was 59·4 per cent. of the whole body of miners; in 1925–26 the percentage was 74·4. One consequence is the existence of a greater number of long service men with long periods of exposure to the silica-dust risk; hence the number of simple silicosis cases has been rising—a curious result of improved conditions. A miner slightly affected has the option of continuing at work, but by so doing he forfeits right to an award for any more serious condition which may develop; if he contracts tuberculosis he is bound to give up work, so as to protect others. The type of miners' phthisis is less severe and more "European" than in 1912, and it takes longer in developing; but the conditions of mining still remain capable of originating the disease in modified form. The old type with extensive fibroid consolidation, wherein the factor of inhaled dust was predominant over the infective factor, has given place to a type in which the infective factor is predominant and the dust factor less prominent. The two factors, however, are closely allied; the dust particle and the tubercle bacillus are each carried by the same type of cell; and the two factors may frequently be concerned together from the first in the production of lesions. Nevertheless a probability exists that, at a later stage, a new or further inhalation infection, aided by a humid, dust-laden atmosphere, carries the tubercle bacillus directly to the lesions. Apart, however, from new infection, silicosis tends to advance, the advance depending on the degree of activity of the infective element present; the direction of progress is towards an ultimate condition of obvious tuberculosis. Hence the regimen of life for a silicotic

[1] Report upon the Work of the Miners' Phthisis Medical Bureau for the Two Years ended July 31st, 1926. Pretoria. 1927. Union of South Africa.

should be that for a case of latent tuberculosis. The tendency to advance is hardly, if at all, influenced by withdrawal from further exposure to silica risk. Clearly both factors must be minimised, the dust hazard and tuberculous infection, in order to eliminate the disease. Much consideration is given to the factors leading to an observed increase in the production-rate of simple silicosis, 57 per cent. of which is accounted for solely by the altered average age of the personnel already mentioned; while a great part of the remainder is due to greater refinement in the detection of cases. The evidence on the whole is encouraging to those who are applying practical preventive measures. The average duration of mining life of those who become silicotic has increased from 109 months in 1920–21 to 130 months in 1925–26; but the incidence of silicosis still falls most heavily upon miners using machine drills. In 1917–18 among European miners 191 cases infected with tuberculosis were detected, compared with 37 in 1925–26. The native labourers are now recognised to be a potent source of infection, and steps have been taken to supervise their health more intimately. Apart from a strict initial examination on engagement any native losing 5 lb. or more in weight in three months, or 6 lb. or more in six months, is set aside for stethoscopic examination; further, any native employed for five years or more is medically examined every three months and is radiographed annually. The native is as liable as the European to silicosis, but seldom remains a miner long enough to develop the disease; he is far more liable to tuberculosis. Over 1000 cases of active tuberculosis, an incidence of 5·5 per 1000 native miners, were detected in 1925–26; in this way native "carriers" are being detected and eliminated. The results of these efforts to remove all sources of tuberculosis from among the mining community numbering nearly 200,000 males will be watched with interest.

THE EFFECT OF ANÆSTHETICS ON THE LIVER.

Dr. S. M. Rosenthal and Dr. W. Bourne [1] consider that the toxic effects of anæsthetics on a diseased liver play an important part in the causation of deaths during anæsthesia. To compare the action of various anæsthetics on hepatic function they have employed two tests. The first of these depends on the disturbance of pigment metabolism, the amount of urobilin in the blood and urine being an index of the damage sustained by the liver. The second is based on the power of the liver to remove bromsulphalein from the blood and excrete it in the bile; normally it is almost completely removed 15 minutes after injection, but if the organ is injured the dye remains in the blood for a longer time. The experiments were done on dogs, and, with chloroform, it was found that brief periods of anæsthesia caused immediate toxic effects followed by functional impairment for eight days, whilst after two hours' administration of chloroform recovery was not complete for six weeks. Disturbance of function could be shown by the bromsulphalein test long after the bilirubin in the blood and urine had returned to normal. Ether, on the other hand, had no effect on pigment metabolism and only a transient impairment was shown by the bromsulphalein test, recovery being usually complete in 24 hours. Nitrous oxide and ethylene, when given with oxygen, so that there was no cyanosis, caused no detectable changes with either test. When, however, these were given in such a way as to produce cyanosis, both immediate and delayed toxic effects could be demonstrated. It is suggested that cyanosis increases the vulnerability of the liver to anæsthetics. Large doses of morphine in dogs were found to act in the same way, and even without anæsthesia they caused considerable depression of function. Rosenthal and Bourne believe that in severe disease of the liver ethylene is the anæsthetic of choice.

[1] Jour. Amer. Med. Assoc., Feb. 4th.

Mr. Wilfred Trotter has been appointed Honorary Surgeon to the King, and Mr. Thomas Peel Dunhill has been appointed Surgeon to His Majesty's Household.

WE regret to announce the death of Mr. Richard Lane Joynt, surgeon to the Meath Hospital, which occurred at Dublin on April 8th, at the age of 61.

Dr. George Chisholm Williams, who died on April 10th at his home in Finchley, had been disabled for many years as a result of radiological work carried out since 1895. Last year he was granted a pension on the Civil List in recognition of "Self-sacrificing services in the application of Rontgen rays to the treatment of disease."

THE Medical Registration Council of the Irish Free State has notified the Minister of Local Government and Public Health that the new Register will be established on May 26th, 1928. After that date no person whose name is not entered on the Register will enjoy the privileges of a qualified medical practitioner in the Irish Free State. In the first instance the Register will consist of those whose names are entered in the General Register with an address in the area of the Irish Free State and of those whose names are entered in the General Register with an address not within the area of the Irish Free State who notify to the Registrar within one month before May 26th their wish to be registered in the Irish Free State Register. While, therefore, every practitioner on the General Register is entitled to be registered on the Irish Register, only those resident in the Irish Free State will be automatically registered; others must signify their wish to be so registered. After May 26th registration will only be effected on payment of a fee.

As a result of visits to Central and Eastern Europe and the United States, the Malaria Commission of the Health Organisation of the League of Nations reported that the number of specialists in malaria was too small for the organisation of an effective campaign against the disease. To remedy this, the Health Organisation has arranged, since 1926, a series of special study courses in malaria for the benefit of doctors who have specialised, or who desire to specialise, in malariology. The courses are divided into two sections: (1) a theoretical course given in suitable institutes and laboratories; (2) practical experience in infected areas where the campaign against malaria is actively carried out. In arranging the study courses, the Health Organisation has secured the collaboration of Dr. Andrew Balfour, Director of the London School of Hygiene and Tropical Medicine; Prof. E. Brumpt, of the University of Paris; Prof. Bernhard Nocht, Director of the Institute of Tropical Diseases at Hamburg; and Prof. Vittorio Ascoli, Director of the School of Malaria in Rome. Instruction will be given in the language of the country where the course is being held. Courses in 1928, details of which are supplied by the Health Section of the League of Nations in Geneva, have been arranged in London, from April 25th to June 13th; in Hamburg from May 7th to June 13th; in Paris from June 1st to July 13th; and in Rome from July 2nd to July 30th.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—A meeting of this society will be held at the Guildhall, Bath, on Friday, April 20th, at 2.30 P.M., when there will be a discussion on Causes of the Decline in Tuberculosis Mortality. The opening speakers will be Sir Robert Philip, Dr. W. M. Willoughby, Prof. E. L. Collis, and Prof. Major Greenwood. Before the meeting the Mayor of Bath will entertain members of the society at luncheon. Those who intend to be present are asked to notify Dr. J. F. Blackett, M.O.H., Health Offices, Sawclose, Bath, not later than April 16th.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXI.

HEADACHE IN CHILDREN.

HEADACHE is a symptom commoner in the adult than in the child. In infants and young children it is infrequent, but after the age of 5 years it becomes increasingly common as the child grows older. Among the reasons for this age-incidence may be mentioned the incomplete ossification and elasticity of the cranium in the early months, the freedom of the young from circulatory disturbances, and their relative immunity from the continued mental stress which produces the headaches of nervous exhaustion. Even apart from these factors, it appears that children are for some unexplained reason less liable to exhibit the symptom. In illustration of this fact may be mentioned the absence of headache in some cases of tuberculous meningitis occurring in children below the age of 6 years, and the unimportance of headache, as compared with vomiting, in young children afflicted with migraine.

Headache can only be recognised in infants by a correct interpretation of the signs which it produces. Cephalic pain, which may be taken to include both earache and headache, causes young infants to put their hands to their heads, scratching and rubbing them at times; it also causes wrinkling of the forehead, crying, and restlessness. Earache is by far the commonest cause of screaming and of putting the hands up to the head, and it is especially frequent in association with teething and the catarrhs of the first two years. Quite apart from earache, true headache may occur in infants, and is often a sign of an organic affection of the brain. Disorders of function, such as indigestion and constipation, do not produce headache at this age. Indeed, constipation in the infant is almost always unaccompanied by the toxic phenomena associated with it in adult life.

The younger the child the more important is the symptom, and the more apt is it to point to cerebral mischief. Headaches should never be treated symptomatically until every effort to reach an accurate diagnosis has been made.

Causation.—In infancy true headache (earache being excluded) may be caused by meningitis, intracranial tumour, and hydrocephalus. In the last condition it is only to be expected when the enlargement is slow and ossification of the cranium advanced. It is not always present in tuberculous meningitis. The persistent crying of syphilitic infants has been put down to headache resulting from meningo-encephalitis. The discovery of such signs as a tense and bulging fontanelle, head retraction, and optic neuritis will give a ready explanation of the symptom.

In children past the age of infancy there are several well-defined groups of conditions in which headache is prominent.

Ocular Headache.

Eye-strain is the commonest single cause of headaches which are prolonged over a period of more than a few days. It seldom occurs before the age of 5 years, the age when most children commence their schooling. Persistent headache without obvious cause at or after 5 years of age should always lead to an estimation of any refractive error which may be present. It originates in minor degrees of hypermetropia and astigmatism more often than in serious refractive errors. The headache of ametropia is seen in its most typical form after school hours, and in this respect contrasts with headaches of toxic origin which occur most commonly in the morning. Overwork at school may of itself be a cause of headache, quite apart from any refractive error.

Toxic Headache.

There are a large number of conditions which may be responsible for toxic headaches. All the acute infections may produce headache, but they are by no means so liable to do so as in adult life. Fever of less than 104° F. hardly ever causes headache, and its presence with a temperature of 100° to 101° should arouse suspicion of tuberculous meningitis. Scarlet fever, enteric, acute tonsillitis, and acute pyelitis, may all give rise to very severe headache, which is safely relieved by giving aspirin in doses of 5 grs. every four hours to a child of 5–10 years. It is but seldom that the headache of acute infections in the younger children is prolonged or severe enough to require any palliative treatment.

Two main varieties of toxic headache will be considered separately: The first of these is that due to digestive disturbances, the second that of juvenile rheumatism.

Digestive Disturbances.—A morning headache occurs in some children who have a prolonged disturbance of digestion. Such children are most commonly below the age of 7, an age when there is a remarkable improvement of digestive power, following the commencement of the second dentition. The children in this group are found to have furred tongues, foul breath, and impaired appetite; constipation and abdominal distension may also be present. For purposes of diagnosis and treatment, the group must be divided into two sub-groups.

First, the digestive disturbance may be dietetic; the food itself may be at fault either in variety or quantity, or the digestive powers of the child may be subnormal. Sometimes the child is being forced to eat even when loss of appetite should have warned the mother to be careful. A common fault is the giving of a heavy meal shortly before bed-time, a procedure only too likely to embarrass a digestion already impaired. Treatment should be directed towards finding a diet which may be easily dealt with, constipation should be corrected, no food (not even milk) should be allowed after tea, and the time of this last meal should be adjusted so that an interval of at least two hours elapses before going to bed. The use of stomachic mixtures such as—

℞ Pulv. rhei, gr. i.; sodii bicarb., grs. ii.; syr. zingib., ♏ vi.; aq. menth. pip. ad, ʒ i.; below 3 years give ʒ i., and above 3 years ʒ ii., before meals; and ℞ sod. bicarb., grs. iv.; spir. chlorof., ♏ ii.; inf. gent. co. ad, ʒ ii.; sig., ʒ ii. t.d.s., a.c.—

are useful but quite subsidiary to the general measures outlined above.

Secondly, digestive disturbance may be secondary to infections of the upper respiratory tract. Disturbances due to acute infections, such as coryza and tonsillitis, are comparatively short-lived, but may sometimes persist for a few weeks after the attack has subsided. More lasting is the digestive upset produced by the swallowed secretions of chronically infected tonsils and adenoids. Such children show the symptoms of indigestion (foul breath, furred tongue, loss of appetite), together with night cough, disturbed sleep, grinding of the teeth, puffy eyelids, and dark shadows round the eyes. An important and suggestive sign, which the physician may be lucky enough to see, is the presence of muco-purulent discharge running down the posterior wall of the pharynx. The tonsils in these cases are not necessarily enlarged, but scarring is often present, while the lymphatic nodes draining the tonsils are palpable. Enucleation of tonsils and removal of adenoids is the correct line of treatment in cases which continue to show such signs over a period of weeks.

Headache due to *juvenile rheumatism* occurs in children of the hospital class above the age of 6 years, and usually in the early part of the day. For the headache of chorea aspirin grs. v. to x., according to age, three times in the day, is useful. In cases of subacute rheumatism with headache, symptomatic treatment is seldom required if the general condition is dealt with.

Cyclical Vomiting and Migraine.

Migraine is not very common in childhood, but it is seen occasionally during the later half of this period. Sir William Gowers pointed out that the migraine of childhood differs from that of the adult in showing a tendency to be accompanied by pyrexia.

There is considerable evidence in support of the view that migraine is manifested in the child by the disorder known as cyclical vomiting. The attacks of cyclical vomiting are often accompanied by pyrexia, and sufferers from this disorder may become liable to typical apyrexial migraine after puberty. On the other hand, the periodicity characteristic of cyclical vomiting is not always found in migraine, neither do most of the cases of recurrent vomiting develop migraine.

A large majority of the recurrent bilious attacks accompanied by headache fall into the group of acetonæmic vomiting, and for these treatment by the daily addition of glucose to the diet will almost invariably be an entirely satisfactory prophylactic measure. For younger children a teaspoonful of commercial liquid glucose given by itself or as an addition to porridge or milk pudding should be taken three times in the day. It is most important that this daily treatment should be followed religiously for as long as the liability to the attacks persists. For older children the dose should be doubled. In place of commercial liquid glucose, barley sugar or powdered glucose may be used. Most mothers become rapidly convinced of the efficacy of this treatment, and there is seldom difficulty in getting them to continue it for prolonged periods.

Endocrine Disturbances.

Persistent headache is found in a certain small group of overgrown children with obesity. The usual clinical picture in these cases is that of a fat girl of about 12 years of age, who is considerably over weight, taller than usual, and subject to severe and persisting headache. Radiograms of the sella turcica are normal. The treatment of the headache is most difficult; phenazone, aspirin, and bromides may be tried, or the following mixture:—

℞ Phenazon., grs. v.; sod. brom., grs. v.; glycerin., ℥ xxx.; aq. camph. ad, ℥ s.s.; sig., ℥ s.s., t.d.s.

In suitable cases extr. thyroid siccum may be tried, but its effects must be carefully watched. Headache is also a feature of dystrophia adiposo-genitalis (Fröhlich's syndrome), and it is often complained of by girls at the age when menstruation commences.

There are other causes of headache in children which do not fall into any defined groups, but must be mentioned briefly. Headache occurs in some 50 per cent. of all cases requiring operation for adenoids; thus it will be seen that adenoids are commonly responsible for this symptom, but the influence of septic tonsils must not be overlooked. Dental caries may be a cause, especially when the headache is very erratic in its onset and disappearance. Uræmia, nephritis, anæmia, trauma, and lead-poisoning are occasional causes. It is also seen as an early symptom of juvenile general paralysis, and, like vomiting, it may be a symptom of hysteria. Sinusitis is a highly exceptional cause of headache in childhood, and only occurs at the extreme latter end of this period.

Headache Without Discoverable Cause.

Even when diligent search has been made for a cause all efforts may prove fruitless. Many cases admitted to a children's ward for headache alone are discharged undiagnosed and unrelieved, thus showing that even when all the causes of this symptom are investigated there remains a residuum of "idiopathic" cases. In this group a family history is sometimes obtainable. The ages when the liability to headache in the parent appeared and disappeared are data on which a guarded prognosis may be based.

SOLARIUM TREATMENT IN SOUTH AFRICA.

BY LEWIS E. HERTSLET, M.R.C.S. ENG.

THE following statement has been prepared with the feeling that overseas colleagues would be interested in the conditions under which sunlight treatment is being given with us. A publicity campaign, organised by the South African Government, has brought our assets of sunshine and spaciousness before the mind of the world, and visitors from Europe, America, and England are finding out in increasing numbers the general benefits of our climate, but from a medical standpoint, however, we are only just beginning to realise the possibilities underlying the scientific use of our all-the-year-round sunlight.

The Johannesburg Hospital.

Here there is a solarium in the children's section, which has been in working for the past two years. This was made possible by the gifts of the local Rotary Club and one of the surgeons to the hospital. It consists of an open-air ward of 12 cots, which opens on to a flat roof with a brick parapet and a brick-tile floor. The cases treated here are practically only tuberculosis of spine or hip in children between the ages of 4 and 14. Most of them come from the Witwatersrand, but a few have been sent from other parts of South Africa. They are given sun in the mornings only, for graduated periods from 30 minutes to three hours; the average stay of the present patients is 15 months. In Johannesburg, also, the flat roof of the recently built theatre block of the *General Hospital* is to be utilised for giving sun baths to certain cases in the wards, but this is not considered a solarium. A movement is now afoot to provide an open-air ward and sunlight treatment in the grounds of the *Convalescent Home* attached to the hospital—this will be for adult (surgical) tuberculous cases only

General Extension of Sunlight Treatment.

An increasing number of practitioners in town and country are prescribing sun baths for those of their patients who can arrange them in their gardens, while some are given at nursing homes, and other cases are sent to private solariums and two or three health institutes in various parts of the country.

At the *Nelspoort Sanatorium* for pulmonary tuberculosis on the Karroo sun treatment has been tried, but apparently not with marked success. It would appear that the altitude is not high enough, and the climate too hot for this method to be entirely satisfactory. The raw native of South Africa believes in the sun to a great extent for certain conditions, and is often to be found, when sick, lying inside the cattle-kraal, but he wisely eschews the heat of the mid-day sun. That the actinic rays benefit him, notwithstanding his brown-black skin, is without a doubt. This would seem to contradict the theory that the pigmentation produced by exposure is a protective against the ultra-violet rays. It appears true for white patients that "the better they brown the better they do"; may it not be that the melanin particles protect against the infra-red rays, which constitute 80 per cent. of the whole spectrum of light? An interesting observation is that patients pigment here more quickly under the winter sun than in summer time.

I cannot state how many artificial sunlight lamps are in actual use for medical purposes in this country, but an agent of Messrs. Siemens (which firm is one of the largest importers of these lamps) has given me the following figures: hospitals, 4; doctors, 13; dentists, 2. The number is naturally small, owing to the small number of our white population, and the

generosity of Nature in giving us so much of the real article.

Very little has so far been done in the direction of analysing the quality of our ultra-violet light: we know that in this climate, with our clear atmosphere, and particularly in the higher altitudes, there must be a very high percentage of the actinic (or as I prefer to call them) "saluferic" rays, both from direct sunlight, sky-shine, and reflected from the clouds, but we cannot state in exact terms what their value is. Some research work in actinometry is now being undertaken, however, by a graduate of the local university.

Some Personal Experience.

Personal experience of over two and a half years has clearly shown me that heliotherapy is applicable to a great many more conditions than the so-called "surgical tuberculosis," and is a much more complicated matter than merely "baking in the mid-day sun." It has also demonstrated to me that most, if not all, of the many factors enumerated below may be reckoned as integral elements of solarium treatment if it is to be given scientifically and successfully.

The *climate* must be entirely suitable, a daily and seasonal variability is good, but there should be no undue heat, cold, moisture, or dryness: such conditions in fact as are available on this part of the high veldt where the winter is cold but dry and sun-shiny.

An *altitude* of over 4000 feet means clearer and cleaner air, with a higher actinic value in the light. The Witwatersrand is 5700 feet above sea-level, which is practically the same altitude as that of Dr. Rollier's clinics in Switzerland.

A plentiful supply of *sunlight* is an obvious necessity. The mean daily hours of sunshine for the following places are:—

Cape Town ..	7·5	While the percentage of the total possible hours are respectively	66
Witwatersrand	8·7		73
London ..	3·8		29
New York ..	6·9		56

The maximum hours of sunshine occur here in the winter months. In this district we get over 3000 hours of sunshine per year; there are only about 14 days in the year in which the sun is hidden all day, while for 134 days there is continuous sunlight from dawn till dusk. In Switzerland a year with 2000 hours of sunshine is, I believe, labelled "a sun year."

The clearness of the *atmosphere* largely affects the permeation of the saluferic rays. Smoke, dust, fog, and mist all act as strong filters of these vital rays. A solarium must be stationed where these untoward factors are reduced to a minimum. The high veldt air is of a wine-like and stimulating character for most of the year.

Surroundings.—Where resident patients are under treatment the grounds should be sufficiently spacious and so enclosed as to ensure quiet, comfort, pleasure, ample air- and sun-entry, together with due privacy.

Supervision.—The highest measure of success can only be attained where the treatment is constantly supervised by a resident practitioner who is *au fait* with the reactions, dosage, and danger-signs, who is competent to make clinical examinations, undertake the necessary observations, prescribe and carry out other forms of treatment, and keep correct records of progress.

The employment of trained *assistants* is a sine qua non as patients often cannot be safely left to take their own insolation ("heliation" is perhaps a happier word!), especially in the early stages of treatment, and many of them need that care and attention which can only be given by a trained nurse. This obviously applies specially to children. Both doctor and nurses should, if at all possible, adopt the practice of taking sun baths themselves.

Here it is comparatively easy for us to plan an *open-air life* for those undergoing treatment. Rooms for eating and sitting with the north aspect enclosed by mosquito (fly) netting only, sleeping porches, cottage tents (with double fly), hammocks, stretchers under trees, these and other arrangements make it possible that at no time during the course is the patient in a closed room. The conditions to be fulfilled by such a *building* are: It must be specially designed; it should face (in this country) north-east, and so allow for the admission of all the available sunshine; it must be cool in summer and warm in winter; cheerful appearance of the interior; pleasant surroundings, and ample air-space are also essential matters.

Sun Enclosures.—Here we have coined the word "helion" to indicate those places where the actual sun baths are given. Special attention needs to be given to these, so that adequate privacy and sufficient air circulation may be provided; radiated heat from floor and walls is undesirable; there must be protection from cold winds, and shade and air baths on warm days should be obtainable. Grass underfoot and walls of thick hedge are possible in this country, and add to the pleasure of prolonged sessions in these helions. Stretchers on which patients lie in the earlier stages; screens for head protection, and space in which more advanced cases can walk about are all essential. Other provision is, of course, necessary for bed-ridden cases.

Dosage.—The quantity of actinic rays reaching the patient is affected by the following physical conditions: altitude, season of the year, angle of the sun (time of day), clearness of the atmosphere, presence of clouds, movement, temperature, and humidity of the air. Some of these vary from minute to minute. To these eight variables must be added the following personal factors which again vary in each individual: colour of skin, pigmenting power, facility of perspiration, blood pressure, age, previous exposure, rise of temperature, &c.

It will be realised that the permutations and combinations of these many factors are practically endless, so that the dose per day of sunlight for any particular patient cannot be rigidly laid down, and a careful study of the physical conditions and personal idiosyncrasies is essential to proper dosage. This is regulated by increasing or diminishing the amount of skin area exposed and the time of such exposure. We find that most patients cannot stand and do not benefit by a full exposure of more than an hour to the great volume of light present at this altitude, even when this is only reached by a careful graduation over a period of 10 or 12 days. Mid-day exposure is practically never possible nor desirable. An over-dose can very easily happen in this climate, but can be avoided by rigid adherence to instructions and systematic taking of temperatures and blood pressures, together with careful watching of skin and other reactions.

A specially planned *time-table* for each individual is highly desirable, especially in the early stages. It helps in the promotion of discipline and gives the patient some plan by which he may take his exercise, rest, bath, meals, heliation, walks, and so on.

In this country *diet* is a matter of some difficulty, but not insuperably so. Variety, palatability, vitamin and caloric content, punctuality and attractive nature of service, heat and digestibility, are all matters that should receive due attention in connexion with food.

Accessibility.—The solarium needs to be within easy reach by road and rail, so that friends and relatives can visit patients, and no strict hours should be laid down in this connexion. Reasonable nearness to a large town is highly desirable from the point of view of obtaining the often necessary help of specialists (X ray, bacteriology, and consultants).

Medicine and Massage.—These need to be prescribed according to the condition and needs of each patient, and in consultation with colleagues sending them for treatment.

Amenities.—Directed occupation, motor drives, wireless, gramophones, motoring, fishing, boating, games, bioscopes, papers, telephone, and other amenities should be available and permitted to all suitable cases.

Record of Cases Treated.

We have here a delightful absence of rickets, while cases of surgical tuberculosis are seldom seen. At our altitude tuberculosis of lungs responds quickly and well to this form of therapy, particularly in the afebrile type. Definite improvement has resulted in paralysis agitans, rheumatoid arthritis, bronchiectasis, and neurasthenia. Cases of secondary anæmia, general debility, insomnia, sciatica, and chronic gastritis have been cured. One case of hypopiesia in a man of 59 was brought to the normal in five weeks. Cases of tuberculous peritonitis, rheumatism, and post-operative convalescence have shown marked progress even with a short course of treatment.

Many other conditions would doubtless respond equally well to the extraordinarily good sunlight facilities available in South Africa as a development of systematic treatment occurs.

Florida, Witwatersrand, Transvaal.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

A Medical Adviser to the Edinburgh Corporation.

THE Edinburgh Corporation have decided that a new appointment of medical adviser to the corporation be created to include the duties of casualty surgeon, medical referee, and medical adviser for all departments of the corporation with certain exceptions, and that the salary for the appointment be fixed at £500 per annum. This is a new and important departure. Formerly the work of casualty surgeon was associated with the professorship of forensic medicine in the University—at least since the date when Sir Henry Littlejohn became professor. Before that time Sir Henry had charge of forensic medicine in an extramural school. The appointment of Dr. Douglas Kerr to the new office is, in a way, a reversion to the former practice; he is now an extramural lecturer. Sir Henry Littlejohn was at once medical officer of health for the city and lecturer in the extramural school. During his tenure of the professorship the casualty surgeonship was associated with the chair. The new office, however, includes the duties of medical referee, and the examination of entrants to the permanent service and claimants for superannuation. It was pointed out from the opposition that the professor of forensic medicine would be deprived of a good deal of teaching material, but Dr. Kerr's appointment was carried by 28 votes to 25. It is, however, possible that some readjustment may be made with the University to secure to University students any advantage there may be in the materials furnished from the corporation's police department. In the recent appointment to the professorship of public health, the medical officer of health was made director of sanitary instruction, and contributes to the work of the public health course. It would be a pity if a chair with such a distinguished record as the chair of forensic medicine in Edinburgh were, in any degree, to suffer for the want of teaching materials. The whole tendency of modern developments has been rather to bring the city into closer touch with the Edinburgh medical schools.

Dr. Kerr, the new medical adviser, was assistant to the late Prof. Harvey Littlejohn for over five years and lecturer in the University. He has "carried on" since Prof. Littlejohn's death both in the work of the chair and in the casualty surgeonship.

Discharged Prisoners.

The Edinburgh Prisoners' Aid Society is appealing for greater financial support from the public. The total expenditure in helping 1341 people last year was £331, of which £179 was received from the prison authorities and £151 came out of the society's funds. These are very small sums for refloating in society 1341 ex-prisoners. It is stated that the help given to discharged prisoners represented in money only 5*s.* per individual, and of this sum a little over 2*s.* per person came from the funds of the society. One wonders whether a sum of 5*s.* is worth anything real in enabling a destitute person to re-establish contact with the industrial world. No doubt the society has many methods of enabling him to establish touch; but as the knowledge of the criminal widens and prisons are reorganised, there is a growing feeling that the criminal's punishment begins, not when he enters the prison, but when he leaves it. It was stated at a recent meeting that the number of prisoners had fallen off enormously and that to-day there were under 200 women in all the prisons in Scotland. The old type of woman prisoner who kept repeatedly coming to prison for being drunk was dying out; but the Borstal class of case was on the increase. The suggested factors of this increase were unemployment and "the pictures." Here, as usual, the most obvious causes are readily accepted as the most real; but it is worth remembering that the juvenile delinquent is not a creature of yesterday or of any single country, with or without "pictures." These short cuts to explanation are not impressive. It is not for want of scientific study that we fail to grasp in practice how deep and elusive the roots of crime are, but I wonder when the trained psychologist is to get his real chance in the police-courts. He is already in the schools and doing good work; it is time he was on the bench and in the prisons.

Royal Victoria Hospital Tuberculosis Trust.

The report of this trust—the pioneer in the Scottish antituberculosis campaign—records a remarkable increase in the number of applications for the admission of young children to the colony at Southfield. The scientific position long maintained by their medical advisers—namely, that tuberculosis is for the most part implanted in childhood—has now become a matter of general acceptance. "It is to the nursery and schoolroom," the report states, "that observation and effort should be directed if measures for the eradication of tuberculosis are to be fundamentally sound and practically effective." The principle of anticipatory detuberculisation is followed at Southfield, the child's physiological resistance raised, and therapeutic measures taken to meet particular issues. The results have proved most gratifying. The committee has reason to believe that not only can evident disease be arrested, but that the process of detuberculisation may be advanced so far that approximate immunity for the future may be expected.

THE EDINBURGH CORPORATION BILL.

WE have already drawn attention to the Bill in which the Edinburgh Corporation seeks powers to control persons suffering from venereal diseases. This Bill is likely to come up for a second reading in the House of Commons on April 19th.

In the following statement received from a Scottish correspondent will be found some of the arguments put forward in its favour, together with an account of local opinion on the subject:—

"The Bill," writes our correspondent, "is the result of a careful study of the situation in Edinburgh by the Medical Officer of Health and the Public Health Committee of the Corporation, who, after mature consideration are satisfied that the voluntary system cannot control or eradicate venereal disease in a reasonable period. They have given it an exhaustive trial, they are satisfied that it is ineffective for the purpose of controlling the disease and preventing infection, and they are of opinion that it must be reinforced. In this view they are supported by the large majority of the local authorities in Scotland and by the staff of medical men and women who are administering the clinics in Edinburgh. The proposals of the Bill have been discussed by the Edinburgh

Division of the British Medical Association which by a large majority expressed itself in favour of all the provisions of the Bill and was unanimously in favour of further legislation to deal with defaulters. The Bill has been made wide enough to cover all persons affected with venereal disease and liable to infect others, so that the powers of the local authority may be extended to defaulters from private practitioners and persons affected who do not seek treatment at all. This avoids penalising those who take the proper course of reporting for treatment, and is in line with the recommendations on this subject of the Trevethin Committee report of 1923. The intention of the Edinburgh authorities is to continue the voluntary system and to reinforce it by measures providing a 'compulsitor,' especially in the case of defaulters. They have safeguarded the voluntary principle in every possible way.

"On March 15th a deputation representing the Corporation of Edinburgh met the Secretary of State for Scotland and the Minister of Health for England. They placed before these Ministers the facts regarding the situation in Edinburgh and strongly urged them to allow the Bill to go for second reading or at any rate to leave it to the free vote of Parliament. The Minister of Health intimated plainly to the deputation that, for considerations of general public policy, they would be compelled to advise the House of Commons not to give a second reading to the Bill and to put the whips on in the vote to oppose the measure. It is unusual in parliamentary procedure for the Government to intervene at this stage of a private Bill. Considering that the Government did not act similarly in the case of private Bills on the same subject put forward by Bradford and by Liverpool, the Edinburgh Corporation feel strongly that they have not been fairly treated. The Corporation met on March 20th and decided unanimously not to withdraw the Bill and to proceed to the second reading. I understand that one of the objections taken to the Bill raises the technical point that as the Bill interferes with the liberty of the subject it should be in the form of a public Bill. It may be pointed out, however, that there is practically no public health measure on the Statute Book which does not interfere with the liberty of the subject, and many of these measures were primarily the result of local legislation, being strenuously opposed in the first place. Edinburgh, for example, had compulsory notification of infectious diseases by a local Act in 1879, and this was followed by the General Notification Act of 1889 which involves restriction of liberty, although many of the infections concerned are less dangerous to the community than venereal disease. One of the main objections to the Bill is that it might drive the disease underground. This, as is pointed out in the report of the Royal Commission, is really a psychological question. It is a striking fact that those who have had actual experience of the working of the present scheme, and are most concerned in maintaining its efficiency, do not entertain any apprehension on this point. In addition, the attendances at the clinics in Edinburgh during the past three months have been maintained and even increased in spite of the publicity which the Bill has received. The other chief objection is that it would be difficult to lay down a standard of cure and that the standard set by the Edinburgh authority might be too high. It is a noteworthy commentary on this objection that it is in those clinics which demand and have insisted on the highest standard of cure that the best attendance rates have been obtained and the number of defaulters are least.

"The Bill is a measure of medical legislation to be administered by the medical profession and designed to prevent the spread of disease. It would undoubtedly be of the greatest benefit to women and children, often innocent sufferers, and under the present system it is impossible to protect them. It would educate the public in regard to venereal disease, but would not give to the outside public any more information regarding sufferers than at present. The local authority and their legal and medical advisers have very carefully considered all objections to their proposals. They are well aware that there are difficulties to be met, but these difficulties in their view are not nearly so serious or so insurmountable as those which are inherent in the present situation. They are asking, as suggested by the Trevethin Committee, to be allowed to try the method they are proposing for an experimental period. They are confident that they can successfully administer the provisions of the Bill and, in any event, they are satisfied that any of the possible disadvantages following on the granting of the powers asked for are trifling compared with the proved disadvantages of the present system.

"The Convention of (Royal) Burghs has recently reasserted its general support of the Bill, and at a meeting to be held on April 12th at the Usher Hall four out of the five M.P.'s for Edinburgh will speak n its favour."

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

Narcotic Drugs.

THE Ministry of Health has appointed a Commission to elaborate a Bill designed to circumvent the trade in narcotic poisons. The first paragraph of the Bill details the drugs which are to be regarded as narcotic poisons; they are morphia, cocaine, codeine and its derivatives, hashish and its preparations, ether, and all natural or synthetic products which have actions similar to those of the above. Persons who import, or attempt to import, such drugs illicitly, or prepare, or try to prepare, them without the necessary licence are liable to a fine of 10,000 to 20,000 lei and one to two years' imprisonment. Persons who keep in their houses, or on themselves, any amount of such drugs, however small, without a lawful motive, or obtain possession of them by means of fictitious medical prescriptions, or try to do so; also persons who, being aware that the prescription is fictitious, yet deliver stupefying drugs to the individual producing it, are liable to six to twelve months' imprisonment and a similar fine. Those who use the said drugs in company, or recommend their use to others, or facilitate their use by another person, either for money or free of charge, or in any other way, are liable to three to six months' imprisonment and a fine of 10,000 to 100,000 lei. Medical men who facilitate the procuring of these drugs, or prescriptions, are liable to two to twelve months' imprisonment and a fine of 10,000 to 50,000 lei. If the offence is repeated they may be prohibited from carrying on medical or pharmaceutical practice for six months or a year. The Bill will shortly be submitted to the Chamber of Deputies for sanction, and it may be hoped that it will soon become law. It should be stated that its drafting was not necessitated by local conditions, but was the outcome of the international agreement signed at Geneva on Feb. 15th, by which all the States agreed to take measures against the abuse of narcotic drugs.

Congress of Thalassotherapy in Rumania.

At the last Congress of the Association Internationale de Thalassotherapie, held at Arcachon in France in 1925, it was decided that the next meeting should be held in Rumania this year. The countries represented in this association are the Argentine, Belgium, Brazil, Canada, Czechoslovakia, Chile, Cuba, Denmark, Egypt, France, Great Britain, Greece, Italy, Japan, Jugoslavia, Luxembourg, Mexico, Monaco, Norway, Peru, Poland, Portugal, Rumania, Spain, Switzerland, Sweden, United States of America, Uruguay, and Venezuela. It is a pity that none of the States lately forming the Central Powers is a member of the association. The organising work at the Rumanian meeting[1] will be

[1] The Rumanian authorities have placed at the disposal of the Privy Council a limited number of invitations to, and programmes of, the Congress, and these will be sent to any duly accredited delegate on application to the Council.—ED. L.

done by General Vicol, President of the Rumanian Balneological Society and the head of the Balneological Section of the Ministry of Health. The chief subject of discussion will be Pott's disease, and among the lecturers will be Dr. Sorel and Dr. A. Delotte (France), Dr. Delchef (Belgium), and Dr. Balacescu and Dr. Manicatide (Rumania). The programme—subject to such slight alterations as may be necessary—will be as follows :—

On May 22nd the Minister of Health will receive the members of the Congress at Herkulesbad, where there are famous thermal sulphur baths. From May 23rd–25th there will be receptions at Bucharest, with inauguration of the Congress by the Minister of Health, a reception at the Town Hall, inspection of medical institutions, and excursions to Sinaia, Brasov, Moreni (the site of the chief Rumanian oil wells), and Slânic Prahova. On the two following days the Congress will meet at Constanza, on the coast of the Black Sea, and will inspect bathing resorts in the vicinity. May 28th and 29th will be devoted to excursions on the Black Sea, and afterwards there will be an opportunity of visiting Constantinople, or the bathing resorts of Govora and Calimanesti, and the monastery of Curtea de Arges. Would-be members of the Congress have to pay an entrance fee of 1000 lei (£1 5*s*.) ; for wives and other ladies of the party the fee is 500 lei. The fee entitles members to reduced prices for board at Bucharest and Constanza, and elsewhere no charge will be made.

Criteria of Recovery from Gonorrhœa.

Lecturing on this subject at a meeting of the Oradea Medical Society, Dr. Adolf Erdös said that the treatment of gonorrhœa ceases when there are no longer any clinical signs of the disease. It is wrong, however, to say that this stage has been reached unless there has been a thorough examination of the prostate, seminal vesicles, vas deferens, testicles, and perineum. It is desirable to make a urethroscopic examination and dilate the urethral canal ; if no discharge is seen in the orifice, and the urine is quite clear, it may be said that there are no clinical manifestations of the disease. Observation, however, should continue for at least a fortnight, and during this period Dr. Erdös advises patient to take easy walks and other light bodily exercise ; he must refrain from alcohol, sexual intercourse, excitement, and staying up late at night. During this fortnight the urethral orifice should be free from any discharge, and the urine, which should be passed into three glasses, should not contain filaments or prostatic crystals (last portion). The presence of some very tiny filaments may be disregarded. During the observation period he recommends that the urethra should be dilated ad maximum, gentle massage being applied above the sound ; after this there should still be no discharge or filaments in the urine. On the sixth or seventh day following the cessation of treatment a powerful dose of gonococcal vaccine is injected as a provocative. If the cure is complete no discharge will be seen as a result. Of these procedures urethroscopy should be left to the last, and dispensed with if possible, as it may do harm by causing trauma.

From the practical point of view, said Dr. Erdös, patients may be regarded as cured if all the above procedures indicate a recovery. If, however, they require certificates to the effect that they are completely cured of gonorrhœa, they should be asked to present themselves again after the lapse of eight to ten weeks, when the secretion of the prostate and seminal vesicles is examined after massage, and the urethra is looked at as far as the sphincter vesicæ. The sediment of the urine is tested, and if the results of these examinations are not regarded as sufficiently conclusive a provocative dose of vaccine may be given. All these tests must give a 100 per cent. negative result, and if they do so the required certificate may be issued without hesitation, and consent given to marriage.

SOUTH AFRICA.

(FROM OUR OWN CORRESPONDENTS.)

The Medical Congress.

THE public opening of the first scientific meeting of the Medical Association of South Africa (B.M.A.) took place at Bloemfontein on March 12th, and it attracted a distinguished gathering. Dr. A. J. Orenstein, the President of the Federal Council of the South African Medical Association, presided, and he was accompanied by Dr. C. Hugh Bidwell (President of the conference), Dr. S. M. de Kock (Vice-President of the conference), Mr. Justice Jacob de Villiers, and Dr. H. P. Brackenbury, who represented the British Medical Association. Dr. Orenstein, after welcoming the visitors from overseas, said that the long struggle to get a Union Medical Act was now happily practically closed. The Senate, they felt sure, would appreciate fully the importance of the measure, and put no obstacles in the way. The Minister of Public Health, Dr. Malan, and the Secretary for Health, Dr. J. A. Mitchell, deserved special congratulation for securing the passage of the Act through the House of Assembly.

Mr. Justice de Villiers formally opened the proceedings. He spoke of two dangers—one was commercialism in medicine, the other was that of ignoring the possibility of advances in medical science being made outside of the ranks of the medical profession, to the great detriment of science as well as of mankind. He appealed to members of the congress to endeavour to spread among the people those broad principles of hygiene that are well established, and about which there is no controversy, and to concentrate on the prevention of disease. Dr. C. Hugh Bidwell then gave an address on Eugenics.

Dr. H. B. Brackenbury stated that he had been sent to South Africa to emphasise the unity of the profession everywhere, and their willingness to seize upon everything contributed by others outside the profession to promote the health not only of the patient immediately before them, but of the community at large. The absence of disease was not sufficient. Their ideal was the promotion of health both physical and mental. A reception, given by Dr. and Mrs. Bidwell, was largely attended, as was also a civic reception in the town hall. A trade exhibition was given in the Reitz Hall, Grey University College, where the leading manufacturers of medical and surgical apparatus, drugs, and fine chemicals were represented.

The Mosquito Problem.

An investigation of the mosquito problem has been conducted by the South African Institute for Medical Research, and the results are published in the reports of the Institute under the title of A Mosquito Survey of Certain Parts of South Africa, with special reference to the carriers of malaria and their control. The investigation has been carried out by Dr. Ingram and Mr. de Neillon, entomologist.

The report notes the various types of mosquitoes found in Zululand and the Transvaal. It describes several new species, and gives much useful information about the life-history of the prevailing species here. The two main carriers of malaria seem to be *Anopheles costalis* and *Anopheles funestus*, which are both widely distributed and both very resistant to climatic and other changes.

An account of the climatic conditions of the malarial areas is given and Dr. Ingram states that granted an accurate return of the spleen rate for the malarious districts of the Union, and a record of the rainfall during the pre-epidemic period, it ought to be possible to forecast the occurrence of malaria in epidemic form in South Africa as is done for the Punjab in India. There appears to be considerable resemblance between the meteorological conditions of both countries, although South Africa is not so dependent on a monsoon for its rainfall.

The report shows how widespread are the carriers of the disease and how relatively easy it would be to

organise an anti-malaria campaign. Up to the present the Government has done little to eradicate the disease, which is rampant in the Transvaal, Natal, and South-West Africa, and even in certain districts of the Cape, but it is hoped that this report may stimulate the Minister of Public Health to consider the organisation of such a campaign.

Plague.

Inspection by the rodent officers of the Department of Public Health shows that during the last few months of 1927 serious spread of plague infection in veldt rodents took place southwards from the Calvinia district into the Ceres basin, as far as a point about 10 miles north of Ceres, and also westward from Bushmanland into Namaqualand, as far as a line about 15 miles west of Springbok and running roughly parallel with the coast. The affected area early this year included Springbok, Garies, and Nieuwerust, and extended to within a few miles of Van Rhynsdorp and about 25 miles northward of the protective belt, which has been cleared of rodents, along the Oliphants River and irrigation canals. The wave of extension was difficult to check, and the indications are that hares, which are numerous in this part of the country, are playing an important part in the spread. The extension of infection into the Ceres Basin is specially important, as it involves an area in which large quantities of grain, forage, and fodder are produced, much of which is sent by rail to Cape Town and other centres. This infected area is only separated from the open gerbille-infested country on the Cape Peninsula side by a mountain barrier, about three miles wide, traversed by the Ceres and Elandskloof passes, with the Drakenstein range traversed by the Tulbagh Pass further west. Measures are being taken to clear these passes of rodents, and thus strengthen the defences in this area.

UNIVERSITY OF LONDON.—The Senate has approved the institution of a Chair of Dietetics as a part-time post at St. Thomas's Hospital Medical School, subject to reconsideration in the event of funds being available. It has been resolved to institute a Readership in Morbid Anatomy and Histology tenable at the Middlesex Hospital Medical School, and a Readership in Bacteriology tenable at University College Hospital Medical School.—Prof. J. T. Wilson has been appointed External Examiner in Embryology and Mr. J. H. Carpenter External Examiner in Entomology for the year 1928.—A Ph.D. Degree in Physiology has been conferred on Hector Alfred Colwell (King's College Hospital) for a thesis entitled Radium, X Rays, and the Living Cell, together with six subsidiary contributions.

Forthcoming Lectures.—A course of three lectures on the Pharmacological Evidence for Current Methods of Treatment will be given by Dr. J. H. Burn, Director of the Pharmacological Laboratories, Pharmaceutical Society of Great Britain, at University College on May 1st, 2nd, and 3rd, at 5 P.M. At the first lecture the chair will be taken by Dr. H. H. Dale, F.R.S. A course of three lectures on Animal Psychology for Biologists will be given (in English) by Dr. J. A. Bierens de Haan, lecturer in experimental zoology in the University of Amsterdam, at King's College on May 4th, 9th, and 11th, at 5.30 P.M. At the first lecture the chair will be taken by Prof. Julian Huxley. A course of three lectures on Anatomy and the Problem of Behavior will be given by Dr. G. E. Coghill, member of the Wistar Institute of Anatomy and Biology, Philadelphia, at University College on May 7th, 8th, and 10th, at 5 P.M. At the first lecture the chair will be taken by Prof. J. T. Wilson, F.R.S. A course of four lectures on the Human Kidney and the Physiological Study of Human Urine will be given by Prof. J. B. Leathes, F.R.S., professor of physiology in the University of Sheffield, at Guy's Hospital Medical School on May 15th, 16th, 22nd, and 23rd, at 5 P.M. At the first lecture the chair will be taken by Prof. M. S. Pembrey, F.R.S. A course of three lectures on Graves's Disease will be given by Dr. John Eason, of the Royal Infirmary, Edinburgh, at the Middlesex Hospital Medical School on May 29th, 30th, and 31st, at 5.30 P.M. At the first lecture the chair will be taken by Dr. R. A. Young. All these lectures except those by Dr. Bierens de Haan will be illustrated by lantern slides. Admission is free. A course of six public lectures on Blood, a Study in General Physiology, will be given at University College on May 15th, 17th, 18th, 22nd, 24th, and 25th, at 5 P.M., by Prof. L. J. Henderson, of Harvard University.

Public Health Services.

A CASE OF ALLEGED OVER-PRESCRIBING BY A PANEL PRACTITIONER.

THE East Sussex Insurance Committee considered last week a report from its Medical Service Subcommittee dealing with the procedure adopted by the Ministry of Health in the case of a practitioner on the Committee's list whose prescribing exceeded the average cost for the area. The practitioner, the report states, was told by the regional medical officer that the cost of the drugs and appliances which he had ordered was exceptionally high, and that the R.M.O. would call upon him for the purpose of discussing the various points, and ascertaining the reasons for the prescribing in question. The report goes on:

The impression of the interview left upon the practitioner's mind was that the R.M.O. had already made up his mind, and did not wish to listen to explanations. There is nothing in the regulations themselves (as distinct from circulars issued by the Ministry) which suggests that officials of the Ministry will have private interviews with practitioners before deciding whether there is a prima facie case or not, and the idea of such domiciliary investigations by the department responsible for the "prosecution" appears somewhat repugnant to ordinary ideas of British justice. However, the Subcommittee realises that in some cases it may result in a saving of time and trouble if the R.M.O. has an interview with a doctor whose prescribing appears to be costly. In order to prevent misunderstandings, however, it would appear to be essential, that the interview should be limited to investigation, that the R.M.O. should ask for explanations only, and should not express opinions of his own, and that, if the explanations which he receives do not satisfy him, the matter should be referred at once to the Panel Committee, without any kind of preliminary warning or rebuke from the Ministry.

Subsequently, the practitioner received from the Ministry a letter which he regarded (and the Subcommittee considers rightly regarded) as a distinct rebuke, coupled with a threat of further disciplinary action to follow. The letter stated that the Minister found it "difficult to avoid the conclusion" that the practitioner had not given due attention to the importance of exercising reasonable economy. The reports adds that letters in similar terms had been addressed by the Ministry to other practitioners in the area whose prescribing showed an excess above the average. The Subcommittee expresses no opinion as to whether the practitioner had, or had not, prescribed medicines and appliances in excess of what was reasonably necessary for the adequate treatment of his patients, but records its opinion:

That, on the facts as stated in this report, while there may have been a prima facie case, which the Ministry might well have referred to the Panel Committee, the practitioner had strong grounds which justified him in thinking that his explanations would have been satisfactory to his professional brethren on that Committee; and that no steps should have been taken to induce him to alter his methods of prescribing, and thereby deprive his patients of their rights and possibly to inflict loss and suffering on them, unless and until the Panel Committee had dealt with the case.

The report concludes: "If it is the right of a practitioner, as it clearly is, to have the issue tried by a committee of his fellow practitioners, it is still more the right of the insured person, who cannot take any action in the matter himself, to receive all such medicines as the practitioner responsible for treatment considers necessary, unless and until the practitioner's methods have been reviewed, and have been found to be unnecessarily costly, by the Panel Committee, and it is from this point of view that the Subcommittee regards the action of the Ministry of Health as tending unduly to curtail the benefits to which insured persons are entitled under the Act, and in some cases to throw an undue burden on the funds of societies."

TYNE PORT SANITARY AUTHORITY.

Dr. W. E. Harker, in his annual report for 1927 to the port authority, writes that foreign infectious

disease is treated in the Tyne Port Floating Hospital, but there were no cases for it to treat. No infectious disease was found among alien passengers, who are mostly examined in the medical room on Newcastle Quay. On board ship 3331 rats were destroyed, 426 by sulphur fumigation in 37 ships, and 2905 by traps in 79; 1684 were black, 1647 brown rats, an unusual equality; all were found free from plague. The water from 30 ships from ports infected with or suspected of cholera was emptied and the tanks cleaned. The chief diseases reported on the preceding voyage or on arrival were: accidents, 200 (10 deaths); feverish colds, 105; influenza, 64 (1 death); enteric, 28 (1 death); heart disease, 16 (9 deaths); consumption, 12 (2 deaths); pneumonia, 4 (1 death). Apparently none of the wheat, sugar, eggs, fruit, or fish imported required condemnation. Two of the 10,499 fishing boats were found foul and were cleansed and deodorised. In 9730 inspections of ships, nuisances were found in 20 per cent. of British, and in 13 per cent. of foreign. There were 326 side ports to refit, 88 defective water-closets, 89 leaking decks, 50 defective stoves. Dirt and vermin were found in about the same proportion. All requirements of inspectors were carried out. The 18 water boats of the port were examined and their tanks found in good condition. Facilities for treatment of venereal disease exist, but no detail is given of their activities.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Bootle.

WE have received from Dr. F. T. H. Wood the first health report of a county borough for 1927.

The population of Bootle at the mid-year 1927 was estimated at 84,970. The birth-rate was 21·4. The death-rate from all causes was 12·2; from tuberculosis, 1·47; from cancer, 1·33; from respiratory diseases, including influenza, 1·5; and from heart disease, 0·9. Some of the death-rates, calculated per 1000 births, were: neonatal, 25·3; infant mortality, 78; diarrhœa and enteritis, 17·6; and maternal from childbirth, 5·5.

Dr. Wood points out that the tuberculosis and school medical services in the northern half of the borough have been conducted too long in unsuitable buildings, and that the proposal of the Education Committee to dispose of the technical school premises, in which some of this work has been done, creates an opportunity for the erection of a special building to house tuberculosis work, maternity and child welfare work and the "minor ailments," and other clinics of the Education Committee. These activities concern a minimum of 600 cases per week. The bacterial examination of 30 samples of milk showed that seven reached the standard of Certified milk, and four the standard of Grade A milk, but that on the other hand nine were grossly contaminated and two contained tubercle bacilli. The public analyst's report shows that of 105 samples of milk, eight were deficient in fat. Fines to the extent of £16 2*s.* were inflicted on six of the vendors. One sample of sausages contained borates.

Bootle, in common with other areas in S.-W. Lancashire, is at present affected by an unusually severe type of scarlet fever. There were 160 notifications, with five deaths. Of the nine fatal cases of diphtheria (including two admitted from Litherland), five died within 24 hours of reaching the hospital, after being ill previously for periods varying from three to nine days. Tracheotomy was performed in six cases, with three recoveries. The death-rate from diarrhœa and enteritis was 17·6, as compared with 6·3 in England and Wales. During the decade 1891 to 1900 the death-rate from tuberculosis was 2·17 in Bootle and 2·01 in England and Wales. Since that period the Bootle rate has only declined to 1·5 during 1926–27, while the English rate has fallen to under 1·0. Dr. Wood points out that this excess in tuberculosis incidence over the country generally is an unfavourable circumstance which also occurs in neighbouring Merseyside areas. The work of the antenatal clinics shows gratifying progress, and during 1927 one expectant mother in every four attended.

There was a small outbreak of puerperal fever in the maternity home. Four cases were classed as puerperal fever and three as puerperal pyrexia between April 11th and 25th. The cases were seen by the consultant obstetrician. Two died and the others made a complete recovery. No explanation could be given for the occurrence, but there was an outbreak of severe septic sore-throat among the nursing staff on April 29th after the puerperal fever outbreak. The neonatal mortality was the lowest ever recorded, the average for the last four quinquennia having been 39·4, 35·3, 33·7, and 34·7. The Merseyside boroughs combine for the purpose of public health propagandism and in June they made a new departure by the appointment of a whole-time medical lecturer-organiser, and it is hoped to put in hand an extensive programme by arousing the interest of educational, religious, political, and commercial bodies. It is mentioned that the Ministry of Health declines to pay the customary 50 per cent. grant for this public educational work in connexion with tuberculosis and maternity and child welfare.

As regards housing, the years 1927 and 1928 are likely to mark substantial progress. The municipal houses built during the last five years numbered 0, 2, 98, 74, and 182. In addition, 252 houses are due for completion in September, 1928, and 123 are provided for in the next financial year. At the end of 1927 the houses in the borough numbered 14,083. Good progress is being made with the scheme for the substitution of portable ash-bins for ash-pits. At the end of the year there were 7000 houses with ash-pits, and the programme for 1928 provides for the conversion of 1500. The work is being done under a provisional order, and the corporation supplies the ash-bin free.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 31ST, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 322 (last week 342); scarlet fever, 1706; diphtheria, 1277; enteric fever, 55; pneumonia, 1885; puerperal fever, 48; puerperal pyrexia, 114; cerebro-spinal fever, 10; acute poliomyelitis, 3; acute polio-encephalitis, 1; encephalitis lethargica, 25; continued fever, 2; dysentery, 61; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 21 counties:—London, 1; Bedford, 1; Chester, 1; Derby, 18; Durham, 82; Essex, 4; Gloucester, 7; Kent, 1; Lancaster, 45; Lincoln, parts of Kesteven, 1; parts of Lindsey, 6; Middlesex, 4; Northumberland, 12; Nottingham, 11; Stafford, 2; Warwick, 8; Yorks, North Riding, 3; West Riding, 70; Brecknock, 1; Glamorgan, 18; Monmouth, 26.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on April 3rd-4th was as follows:—Small-pox, 4; scarlet fever, 1589; diphtheria, 2407; enteric fever, 32; measles, 1576; whooping-cough, 134; puerperal fever, 16 (plus 15 babies); encephalitis lethargica, 70; "other diseases," 34. At St. Margaret's Hospital there were 12 cases of marasmus, and 11 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (0) from enteric fever, 164 (88) from measles, 9 (2) from scarlet fever, 55 (13) from whooping-cough, 33 (7) from diphtheria, 47 (11) from diarrhœa and enteritis under two years, and 135 (18) from influenza. The figures in parentheses are those for London itself.

Of the 76 fatal cases of measles outside London 10 were reported from Sheffield, 7 from West Ham, 6 from Worcester, 4 each from Plymouth and Salford, and 3 each from Croydon, Brentford and Chiswick, Willesden, Walthamstow, Bristol and Bolton, while the figures in Edinburgh, Glasgow, and Dublin for the same week were 6, 13, and 6.

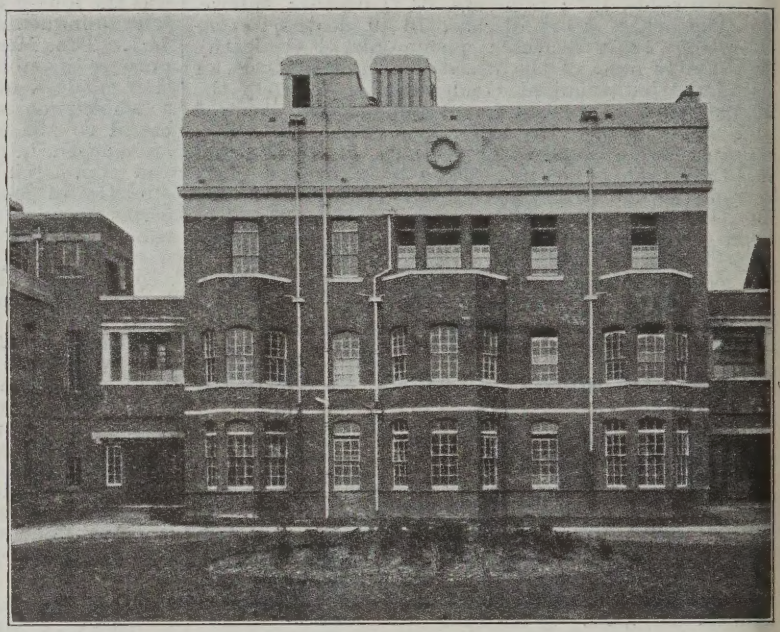
The number of stillbirths registered during the week was 309 in the great towns, including 59 in London.

TRANSFORMING THE "POOR-LAW INSTITUTION."

HALLAM HOSPITAL, WEST BROMWICH.

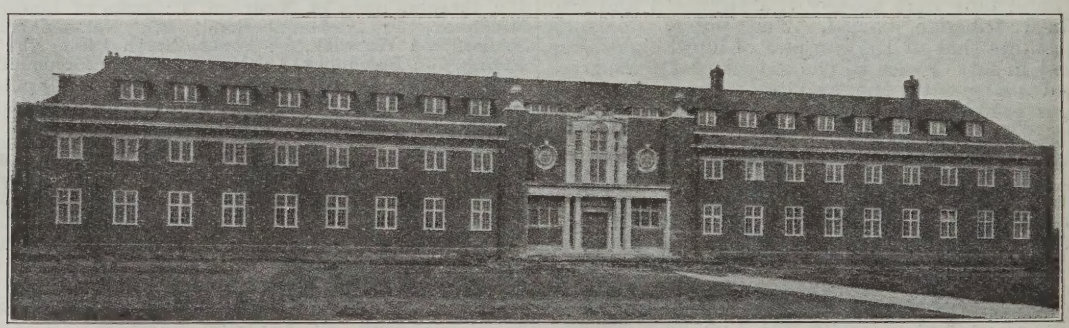
West Bromwich is one of the string of growing industrial towns—Walsall, Wednesbury, Dudley—which stretch to the north-west from Birmingham to Wolverhampton. Of no one of them can it be said that it is "nigra sed formosa," but they are nearly always busy and prosperous and their municipal consciousness is acute. Nowhere is it more acute than at West Bromwich, which has just set so admirable an example to administrators of the poor-law that, were it to be quickly and widely followed, not only would Mr. Chamberlain's scheme for converting the boards of guardians into poor-law committees of the councils become much more difficult to carry out, but a momentous change would come over the hospital situation by levelling up the poor-law institutions to the status of the best voluntary hospitals and easing the ever-increasing pressure upon those institutions.

Three years ago the West Bromwich board of guardians found itself in possession of a very unattractive workhouse infirmary "all of the olden time," a relic of the days before the modern hospital had been evolved. The cheerless wards had walls of unplastered brick which, although painted, looked cold. The floors were so badly worn by years of scrubbing as to be dangerous, and the wards were warmed by large central stoves with flues going up through the ceiling. There was no electric light, no operating theatre, no laboratory, no X ray department, and a temporary nurses' home of corrugated iron. Operations were done in a dark side-room, inconvenient in every way and destitute of proper instruments, cupboards, and fixtures. In 1925 the guardians determined that the deformed should be transformed without loss of time. The whole of the wards were re-floored with polished oak, central heating and electric light were installed, and hospital beds and fixtures of the latest designs were put in. On the male side balconies with completely open fronts were erected, and on the female side a roof ward was constructed. Within a few months of beginning the work patients were being received in rapidly increasing numbers into the renovated wards, and by degrees the whole of the building was improved out of recognition, and furnished with complete modern equipment and appliances at a cost of a little over £100 per bed. A new nurses' home with 70 beds has been built and is shown in the accompanying illustration. The infirmary was then re-named "The Hallam Hospital," and, by the consent of the Ministry of Health, became a self-contained institution. The practical result was soon apparent. The 120 operations of 1926 became 924 in 1927, and the number of admissions grew in the same period by 669; there are now three resident medical officers and there are 52 probationer nurses whose teaching and training have been entirely reorganised.



Part of the renovated hospital.

A fortnight ago, when Sir William Willcox opened the administrative block, the X ray department, and the nurses' home, he was well justified in saying that the West Bromwich guardians "had done something which would occupy the attention of the country, the Government, and the nation as a whole." He reminded his hearers—what, we fancy, is not yet generally understood—that when a poor-law infirmary is converted into a municipal hospital the dreaded stigma of pauperism is removed. He commended the fine example set by West Bromwich, and expressed his belief that it would be followed by a similar advance in hospital improvement and reorganisation throughout the country.



The new nurses' home.

Parliamentary Intelligence.

HOUSE OF COMMONS.

THE EASTER ADJOURNMENT.

THE House of Commons adjourned for the Easter recess on Thursday, April 5th, until Tuesday, the 17th.

TUESDAY, APRIL 3RD.

NATIONAL HEALTH INSURANCE BILL.

Mr. NEVILLE CHAMBERLAIN, Minister of Health, in moving the second reading of the National Health Insurance Bill, said that 16 years ago Mr. Lloyd George embarked upon a new and extraordinarily interesting enterprise for the purpose of providing medical benefits and advice for all classes of the population who might be in need of them. The scheme was one of national insurance based upon a sort of triple partnership. The contributions from the workers were supplemented by other contributions from the employers and from the State, with the result that it was found possible to offer benefits quite out of proportion to the sums that were contributed by the beneficiaries. On the whole, after a review of the operation of the scheme during the past 16 years it might be said with confidence that the principles upon which it was founded had proved to be sound. There had, of course, been many changes in the details. The changes arose partly from the lessons of experience, but in large measure they were due to the special circumstances induced by the War and by post-war conditions, and even now they could not expect to have reached finality. The national health insurance scheme was a tremendous undertaking. Under it there were to-day some 16 million people insured in this country, each of them paying a weekly contribution which individually only amounted to a few pence, but when added together the contributions formed a tremendous aggregate of about £25,000,000 a year. The societies and branches of approved societies which received these sums numbered about 7000, and they distributed benefits in small sums, mostly not exceeding £1, up to the total of about £30,000,000 a year. The present Bill was a further attempt at simplification of machinery, although it also contained some improvements of substance. It was founded principally upon a recommendation of a Royal Commission appointed in 1924 and which after a year and a half of laborious work and examining 200 witnesses, reported in 1926. The present Bill had been approved by the Consultative Council and the approved societies generally and would be grievously disappointed if the measure did not pass. The most interesting clause, and that which would be most generally approved, was the first, which dealt with the case of the man who was unemployed because he was genuinely unable to find work for which he was capable. The first question was what penalty or loss, if any, should be exacted from him on account of arrears? The second question was how long and under what conditions should such a man be continued in insurance after he had ceased to be employed and therefore to make statutory contributions? It seemed on the face of it undesirable that for a circumstance that was agreed was not the fault of the man he should be deprived of his cash benefits, and accordingly the Royal Commission recommended that some further provision should be made which would protect from all loss and all penalty a man who had fallen into arrears with his health insurance contributions on account of his certified unemployment. The Prolongation of Insurance Act, 1921, which was still in operation, had been viewed with increasing dissatisfaction by those who were administering health insurance. The time had come when that Act should be put an end to and some better scheme substituted for it. In the third schedule of the present Bill they were repealing the 1921 Act and substituting for it a completely new scheme which was to be found in the first clause of the Bill. Under that clause they were providing that all the penalties for arrears of contributions incurred because a man was genuinely unable to find employment should be abolished. That meant a loss to the approved societies estimated at about £680,000, and it would be too much to expect that the societies should find the whole of that amount. They had a source from which help could be given in the stamp sales account. They estimated that a sum of £500,000 a year would be available—a sum which would be subject to reduction as the figures of unemployment went down—to compensate the approved societies for the sums which they would lose. In this clause they had the largest concession to the insured workers and the biggest simplification of machinery that had been introduced into the national health insurance scheme since its inception. They were extending the period during which a person after ceasing to be employed could have free insurance with full benefits from one year to one year and nine months on the average. If at the end of that time he was still unemployed and could show that during the whole period he had been available for work but had been unable to obtain it, he would be given another year during which he would be maintained in insurance and entitled to all benefits subject to the condition that his cash benefits might be reduced to an amount which was not to be less than half the standard amount. It was also provided in the clause that where a man had been previously insured for ten years and on reaching 60 years of age fell out of employment he would be kept in insurance year after year provided that in each year he could show that he was available for but unable to obtain work.

Additional Benefits.

The question of additional benefits, and particularly dental and ophthalmic benefits, was a very important matter. Its importance lay particularly in this respect that these treatments were largely preventive as well as curative in character and that the large sums of money amounting to about £4,000,000 a year now being spent by the approved societies on dental and ophthalmic benefits might be expected in due course to bring their reward to those societies through the improvement of the general health which they were calculated to produce. It was a striking fact that while the administration of medical benefit was carefully safeguarded in the original Act, and while conditions were laid down in the body of that Act for that administration and the Minister was given power to make regulations still further to elaborate those provisions, nothing of the kind was to be found in the original Act in regard to additional treatment benefits. Now, however, that they had reached their present pitch of development it was very necessary that some similar care should be taken in regard to dental, ophthalmic, and other additional treatment benefits to see that the money was properly expended and to the best advantage of the insured people. In Clause 14 (3) the Minister was given power to make regulations governing the administration of any additional treatment benefit and the general arrangement of services under which the treatment was to be provided. The Consultative Council, recognising how necessary it was that the approved societies should be able to command an adequate dental service at a reasonable price, recommended the establishment of a joint committee to deal with the matter, and accordingly a committee representative of the dental profession and of the approved societies and known as the Dental Benefit Joint Committee, had been set up to regulate the conditions between the societies and the profession and to ensure the proper working of the service. On the whole he thought the joint committee was to be congratulated on having worked with a considerable amount of success, but there had been this difficulty, that it was not a statutory body and had to work by persuasion. One of the things that he desired to do was to make regulations which would enable him to give authority to this joint committee to ensure that any decision that it came to should be made binding and effective on all the approved societies coming under the scheme.

Dr. VERNON DAVIES: And on the dentists?

Mr. CHAMBERLAIN said that was so. They hoped to get a similar committee set up to deal with ophthalmic additional benefit. There seemed to be a great amount of confusion in connexion with the subject of dental clinics. Judging from his own correspondence he was convinced that many members of the medical profession had altogether exaggerated what was in contemplation. There was no intention of doing anything more at present than embarking on an experiment or two in order that they might thoroughly explore the advantages or disadvantages of the system of dental clinics. The argument in favour of the clinic was that where they got a dense population and could rely upon a steady flow of patients they could get in a clinic a standard of equipment and of specialisation among the staff which it would be unreasonable to expect from a single practising private dentist. He supposed that the argument against the clinic was that it was going to drive out the private practitioner and set up a monopoly. The matter had been discussed by the Dental Benefit Joint Committee, and they did not come to any conclusion except this, that they thought it very desirable that an experiment should be made. If this Bill passed it was his intention to make regulations for the setting up of experimental clinics, one or two perhaps in London. In no circumstances could he contemplate abolishing the free choice of dentists. No one must be compelled to go to a clinic if he would rather go to a private practitioner, and it certainly would be a condition of the acceptance even of an experimental clinic that there should be adequate representation of the profession upon its management.

Dr. DAVIES: Are we to understand that the consent of the local dental profession will first of all be obtained before the clinic is established?

Mr. CHAMBERLAIN said that he did not think that he could give any assurance to that extent, certainly not at that stage.

But he did not anticipate that they would have any difficulty in selecting the most suitable place for an experiment of this kind where they would not arouse any violent feeling of hostility on the part of private practitioners in the neighbourhood.

Deposit Contributors.

Under a new scheme which was to be found in Clause 10 people who on account of bad health could not get into an approved society were going to be formed into a new section of deposit contributors which would be called the Insurance Section and they were to be entitled not only to the equivalent of their own contributions plus the State contributions, but to all normal statutory benefits given under the original Act. Special precautions had to be taken to ensure the solvency of the scheme, because admittedly all these would be bad lives, and therefore they had to supplement the contributions of the deposit contributors themselves. On a valuation it turned out that there was a deficiency, and they had taken power to come on to the central fund in order to make good that deficiency. With regard to the motion for the rejection of the Bill which stood on the paper in the name of Mr. Rhys Davies, the Government could not see any way by which they could bring into the national health insurance scheme those persons who did not stand to any other person in the relation of employed to employer, but the definition in the original Act of the meaning of "employment" did exclude certain classes of workers who were really employed, but who were cut out under the technical objection that they were not under a contract of service. Those were people they hoped to bring in and they included timber fellers, hay cutters, stone breakers, building subcontractors, piece-masters or sub-contractors in various trades, hedgers, ditchers, thatchers, drainers, market porters, slaughtermen, and share fishermen.

An Administrative Measure.

Mr. RHYS DAVIES moved:—

"That this House, whilst prepared to welcome improvements in National Health Insurance, cannot assent to the second reading of a Bill which fails to recognise, in the light of modern conditions, the necessity for making the scheme more national in character by establishing the right of entry to many persons now excluded, neglects to make better benefits possible by restoring the State contributions of which the National Health Insurance Fund has been deprived, and fails in many respects to carry out the recommendations of the Royal Commission."

He said that it was a travesty to state that this Bill was brought forward as a result of the recommendations of the Royal Commission. Out of 122 separate recommendations of the Commission the Bill only contained 32. In fact the Bill was purely an administrative measure and the big questions affecting the health of the 16 million insured people of this country were left entirely untouched. He would like the Minister to explain what was meant by Clause 3, dealing with medical charities, particularly in South Wales. He understood that some of those medical charities were doing excellent work, and he hoped he might be pardoned for a little suspicion that the medical profession were influencing the Minister of Health unduly in that respect.

Lieut.-Colonel FREMANTLE: Never.

Mr. DAVIES said that before they could consent to the abolition of those medical charities he thought they must secure evidence as to whether there was any abuse of the privileges granted them under the original Acts. The two most important recommendations of the Royal Commission related to the pooling of surpluses and to the abolition of insurance committees, and this Bill touched neither. The Minister seemed to have avoided Clause 11. The Royal Commission was very emphatic that something more should be done in connexion with maternity benefit and the case of married women in general under the national health insurance scheme. Clause 11 did make the position of married women very much clearer, but it did not touch those issues raised by the Royal Commission—the terrible tragedy of maternal mortality in this country, about 3000 women dying annually in childbirth in this country. This Bill did not touch that problem in the least. He wanted the Minister to safeguard the interests of the insured persons by making it compulsory on the approved society to include words to the effect that if the insured person failed to go to a clinic he could still choose his own dentist or optician. He had no criticism to offer on the clause relating to penalties except one. He hoped that the Minister in dealing with penalties by regulation would see that whatever penalties he inflicted on the administrators of approved societies and insured persons he would inflict similar penalties on the medical profession, dentists, and opticians who might transgress the law. Some members of the medical profession were issuing medical certificates definitely with a view of increasing their panel practice and as far as he knew there was no provision to deal with cases of that kind in this Bill. If it was proposed to give to insurance committees ultimately the administration of some benefits which were to-day administered by approved societies the Minister of Health would find himself in a difficulty with the Consultative Council. If there had been any abuse at all in connexion with the administration of the National Health Insurance Act he was convinced that it occurred under Section 26. What had been done had been done probably strictly within the wording of the section; but it had not been done very honourably. He supported the full repeal of that section. If any approved society wanted to do anything by way of clinical work or granting money towards charities or hospitals it ought to do it clean and above board. The Royal Commission recommended that the scope of maternity benefits should be extended to cover medical and midwifery services in addition to cash benefits. It would be interesting to learn why that provision had not been included in the Bill. The Commission further recommended the extension of the scope of medical benefit in respect of dependents of insured persons in receipt of sickness or disablement benefit to improve provisions at the time of pregnancy and childbirth, the provision of dental benefit as a normal benefit, and above all that the insured population should be entitled to specialist services as well as ordinary medical practitioner services. Were it not for the fact that the State grant had been reduced the majority of societies would have been able to pay for specialist services.

Sir KINGSLEY WOOD said that the fact there had been no provision made in the Bill for specialist services had nothing to do with the Economy Act.

Mr. DAVIES said that the Bill was a very small contribution to the problem of national health insurance. It did not assist in the solution of the health problems of the country. What about cancer and rheumatism? Nothing was done in the Bill to deal with those diseases. When they compared the Bill with the recommendations of the majority of the Royal Commission he thought that the Opposition were justified up to the hilt in moving this amendment and carrying it to a division.

Mr. WHITELEY seconded the amendment.

Points Concerning Doctors and Dentists.

Lieut.-Colonel FREMANTLE said that there were certain points which naturally concerned very closely the medical and dental professions, and he wished to voice one or two of the feelings on those points. The medical profession generally would bless the Bill in certain parts strongly and in the other parts they would find it good in less degree. On the whole there was no definite provision in the Bill to which serious objection could be taken by those who were concerned in the working of this wonderful and beneficial scheme of insurance. He wished to call attention to the fact that the dental profession were naturally very much concerned, but they would be partly reassured by the statement which the Minister had made that afternoon. He (Colonel Fremantle) could speak perhaps with greater conviction for the dentists inasmuch as it was a friendly profession for which he had no direct responsibility, but he had this from the body representing the dental profession. There were three points which they hoped to see definitely established. The first was that the insured person should have the same freedom of choice of his dentist as he enjoyed with regard to his medical adviser. He thought that the House had had a very definite categorical statement that would be satisfactory to the dental profession. The second point was that the acceptance of any agreement as to fees and conditions of service arrived at after free negotiation by representatives of approved societies on the one hand and of the dentists on the other, should be subject to the approval of the Minister. The difficulty was that they met with collective bargaining everywhere. Unless the results of collective bargaining were made to hold with all parties concerned, especially with those who were less inclined or less able to carry out a bargain, the main object of collective bargaining fell to the ground. He hoped that there would be an assurance given on that point. The third point was that there should be no lay interference with the professional discretion of the dentist in the treatment of his patient. All those concerned with the administration of these Acts knew what was implied in that proposal. Always the criticism by the professional men of the approved societies was that instead of simply confining themselves to administration the approved societies interfered with the actual professional treatment, which only a professional man was really able to control and to criticise.

Sir KINGSLEY WOOD asked Colonel Fremantle to explain a little more what he meant.

Lieut.-Colonel FREMANTLE said that he meant that the difficulty of any lay control of professional persons was that in these matters they did interfere with the actual professional side. It was for that reason that they had their supervising officers. The doctors were naturally very sensitive. He thought that was really the only reason why sometimes there was friction between the professional men and the approved societies. It was for that reason that one

uld not accept the suggestion made by the mover of the nendment that the Insurance Commissioners should be ne away with and their duties given to the approved cieties. That raised the old original criticism that was velled against the Insurance Bill. It was obvious that proved societies could not properly administer these edical matters. The insurance committees were formed order that they might get a better idea that the benefits be administered. It was quite true, also, that the Royal mmission suggested that the duties of the insurance mmittees should be distributed to the appropriate local thority. Obviously it must be a matter of some concern them all that that proposal of the Royal Commission had t yet been acceded to. That proposal was not, as Mr. Rhys avies had said, to refer these duties to the approved cieties. It was to break up these duties and distribute them the appropriate local authorities. He supposed that the ason was quite clear. The whole question of local govern- nt was now the subject of discussion by a Royal Commis- n, and they must wait for the result of that before they uld see how the local authorities were going to be so ranged that they could properly have those duties placed on them. He hoped that they might be able to look ward before very long to having the result of the Royal mmission brought before the public and that House, d that it would then be put into action and not simply geon-holed. When they got the whole subject of local vernment cleared up and put on a systematic basis they ped to have this question of the future of insurance mmittees decided. He was quite sure that the functions the insurance committees ought to be blended with those the health authorities generally. One of the main criti- ms of the insurance system was that, whereas it was largely roduced by Mr. Lloyd George as a measure for the preven- n of sickness, it had failed in the prevention of sickness to very large extent. He did not say entirely, but to a very ge extent, the amount of sickness among insured persons mained very much the same, although he believed that the id of treatment applied had curtailed each case of sickness a considerable extent. The system certainly gave relief, t for prevention it was of very little advantage. One of e objects put forward in connexion with the original Act s definitely to link up the question of prevention and the estion of sickness by making a special provision by which, nen any particular area was found to be suffering from a ry excessive amount of sickness in any one respect, ps could be taken at once to turn the whole services of the surance Act on to that particular area. That had been nd to be impracticable. Why? Because the measure was roduced originally independent of the existing health ganisations. This was a danger that they constantly d in that House. They seized upon a new idea, they roduced a new Bill with a new scheme of organisation, d a new set of committees, or even of actual authorities, d a new set of officials all the way through. They thus ded to their burdens while diminishing certain others. ey had to use the actual machinery they had, and to prove it. He thought that local authorities might be used the central authority for administering medical benefit der this Act.

Maternity Service.

There was one special form of benefit which he was sorry s not provided for as an additional benefit. That was endance in cases of maternity. The answer of the Parlia- ntary Secretary no doubt would be that maternity benefit s provided by a money payment to the mother, who was ponsible for providing the midwife or having maternity vices. The objections to it were fairly obvious. In too ny cases the money was required so urgently for other rposes that it was not sufficiently used for the midwifery vices that were so necessary. He was glad that a com- ttee was to be set up to inquire into the training and supply midwives. When that committee reported he had not the st doubt that it would show that for a long time the mber of midwives in the more scattered parts of the ntry had been diminishing and the immense difficulty getting women to go into that important service. They l to record at the present time the loss of 3000 to 4000 thers as the result of childbirth, and they must therefore e some action which would increase the midwifery services the country. They would not be able to get a better vice in this respect unless they could make the profession ractive to the type of educated girl who would want to fil these duties properly. It really came down to a uniary benefit, and he would like to see some provision roduced into the Bill which would enable a fund to be set de for the general purpose of improving the remuneration midwives. He hoped that the preventive aspect of urance might be always kept uppermost and that, as y worked this system during the course of years, they ght see in what way they could use this sum of £25,000,000 £30,000,000 a year, not merely for the relief of trouble, for the prevention of preventable sickness and disease.

Family Medical Benefits.

Mr. HAYDAY, in supporting the amendment, urged that the Bill should make provision for family medical benefits. This question had become a very important one for many reasons. He did not know whether, if all the surpluses accruing to the approved societies were pooled they would provide a sum sufficient to give medical benefit to the dependents of insured persons. He wished to call attention to a question of administration. Approved societies sent a large number of those people on sickness benefit to the regional medical officers for examination. That was done in the interests of the benefit fund of the approved society, but the payment of the expenses incurred came from the administrative fund of the society. Such payments should be allowed to come from the benefit fund itself, because if they were to flow continually from the administrative account the administration was likely to be affected, and they would not get that efficient supervision which was desirable. He suggested also that there should be one all-inclusive scheme, amalgamating all the present social services under a separate department. That would avoid constant piecemeal legislation.

Major GLYN, speaking as chairman of the Federation of Rural Friendly Societies, said he believed, with the exception of minor points, which he hoped could be disposed of in Committee, the Bill deserved the support of everyone. If they could encourage more prople to take an interest in the friendly society movement it would go forward still further and foster the work done by them. Then, indeed, they would have greater health in the rural districts of the country and greater happiness in the homes of the people.

Grants to Charitable Institutions.

Mr. MELLER, in supporting the Bill, said that reference had been made to the effect of the amendment of Section 26 of the original Act and one hon. Member had said that there had been abuse of that section which enabled the approved societies to make grants to charitable institutions to meet special cases of emergency—cases where their members might require some special treatment from the hospital and which they could not obtain unless some contribution was made to the funds of the hospital. That was a right and proper provision, but some societies had used it as a means of anticipating the additional benefits which ought only to be declared at the end of the quinquennium as a result of the valuation. The Minister did not seek to take away from the approved societies the opportunity of making contributions, but he said, quite rightly, that if they realised that it was desirable to provide contributions to charitable institutions for the benefit of their members they ought to declare it in their list of additional benefits. Those societies which were not in the fortunate position of having a surplus could make application to the Minister and permission would be given in satisfactory cases. In regard to clinics he hoped the Minister would be prepared to accept an amendment making it quite clear that free choice, whether of dental or optician, was the inherent right of every insured person. In the North of Ireland medical benefit was not given and the result was very unsatisfactory. It was suggested by some societies that they ought to have the right to exclude members in Northern Ireland from participation in general valuation until Northern Ireland brought in a system of medical benefit. The view they put forward was that the clause was unfair to their members in the English and Scottish societies which had members in Northern Ireland. He hoped that the Minister of Health would consider that question. The overwhelming opinion expressed by the people concerned was against the abolition of insurance committees. It had been said that insurance committees had lost much of their virtue and had become mere recording machines; but it was a fact that in those districts where the insurance committees had lived up to their responsibilities and carried out their duties as required by the Statute they had become very helpful and very desirable bodies.

Miners' Medical Aid Societies.

Mr. MORGAN JONES said there were in South Wales institutions known as miners' medical aid societies. There was a considerable measure of apprehension among them as to what precisely the Minister of Health sought to do through the medium of Clause 3 of the Bill. These societies had existed for a very long time and after some difficulty were recognised 17 years ago at the passing of the original Act. He believed they had something round 40,000 members and, if they included dependents, the number would exceed 100,000 for whom medical services of various kinds were being provided through the medium of these organisations. But they had had to face opposition from the British Medical Association and also they claimed from the insurance committees. These bodies operated very largely on coöperative lines. The objection, he believed, generally came from the British Medical Association—and there had been pretty severe and sustained fights on the issue—that these societies

had a larger measure of lay control even than was found under the system of insurance committees. It was felt that Clause 3 gave the Minister power to terminate the existence of these societies. He did not want to develop an attack on the doctors generally in this matter, but he was entitled in defence of his constituents to submit a case in support of these societies. They drew a contrast between the treatment meted out to these medical aid societies and that meted out to private panel practitioners and the contrast was one which induced them to believe that the scales were heavily weighted against these medical aid societies largely because they were subject to the ban of the British Medical Association.

Specialist Benefit.

Dr. DRUMMOND SHIELS said that Members on his side of the House were all agreed that the Bill, so far as it went, was desirable, but it did not go to anything like the extent that was called for in any amendment of the National Insurance Act. As a response to the recommendations of the Royal Commission the Bill was seriously inadequate. The Minister of Health and his department were not primarily to blame for that. They found here, as in connexion with so many other matters, the hand of the Treasury, which prevented so much being done that the House felt ought to be done. Economy in these days was necessary, and the Treasury must exercise restraint in many directions, but the health of the people was one direction in which any so-called economy was misplaced, and where true national economy was to provide adequately for health and prevention of disease. The first suggestion of the Royal Commission was in regard to specialist benefit. The Commission said: "While it has been inevitable hitherto that medical benefit should be confined to a general practitioner service, this limitation has detracted from the value of the benefit and its removal is urgently desirable." Then, in the order of desirable extended benefits recommended, the specialist service was given first place; next came allowances to dependents, and then provision of additional maternity benefit. The question of specialist benefit was of great importance. If the lowering of the State grant had not prevented the provision of specialist benefit why was it that they had not got it, and why was it that there was no early prospect of getting it? The present position in regard to specialist benefit for an insured person requiring a consultation or operative treatment was exactly the same as that of an uninsured person. Unless it was an urgent case, which would be admitted to the voluntary hospital immediately, he came on the hospitals' waiting-list and had to take his turn, with the consequence, as happened in so many cases, that treatment was delayed beyond the time when it would be of the greatest advantage. The recent Commission on Hospitals in Scotland stated that there was a waiting-list of no fewer than 5000 in the case of the four big Scottish hospitals, and that at least 3000 more beds would be necessary to provide adequate hospital accommodation in Scotland. A condition of affairs which left the insured person dependent on that source for specialist benefit was obviously unsatisfactory. Ordinary ailments could be dealt with by the general or panel practitioner. The more serious cases might require operative treatment, the very latest laboratory appliances, X ray or light treatment, and others required aids from which, at present, the insured person was shut out. There ought to be no class distinction in the provision of medical and surgical skill. The finest medical and surgical skill ought to be assured to the very poorest of our population. Yet here they had a scheme which purported to be a national scheme for the provision of medical service for the insured persons who contributed to it, and surely the Royal Commission were right in pointing out that so long as specialist treatment was withheld, the system was unsatisfactory and did not meet the needs and the rights of its members. The question was obviously linked up with the hospital question, which this Bill did not tackle at all. The voluntary hospitals had repeatedly made requests for allocations from the Insurance Fund proportionate to the number of patients they treated, but all they had here was a permissive clause which would enable societies to make contributions to hospitals. Before the Economy Act was presented to the House certain approved societies did make contributions to hospitals, but since that Act had come into operation it had been difficult or impossible for them to do so. Now they were to be permitted to give donations to count as medical benefit; but that would not meet the case. Either an allocation of money per head, or some other financial arrangement between the insurance Fund and the voluntary hospitals would be necessary. It was desirable for two reasons. In the first place in order that the insured persons should not, as now, get specialist treatment as charity, and, secondly, in order that the voluntary hospitals, or even, as they expected might be the case soon, municipal hospitals, should be assisted to carry on the difficult task of finding the necessary funds. Maternity benefit had been spoken of and he was very glad to hear Colonel Fremantle emphasise so strongly the need of nursing and medical service as well as financial assistance. The Queen had lately called attention to this subject, and it was a matter of some concern that for 100 years they had made no improvement in the figures of maternal mortality. In England and Scotland they had some six or seven deaths per 1000 births and in many of the industrial and poorer districts the mortality-rate was up to 11 and 12 per 1000 births. That was a very unsatisfactory state of affairs, and as Colonel Fremantle had pointed out, the provision of efficient nurses and midwives was one of the best ways of meeting the situation. He commended Colonel Fremantle's suggestion that through the national health insurance organisation means should be found for training and supplying more midwives than were at present available. There were few subjects on which Members of that House would more willingly coöperate than in making it more safe for the mothers of our country to discharge the great task which they undertook for the nation. Similar considerations applied to the question of dependents' benefit. The wives and children of insured persons ought to be within the scope of the scheme, otherwise it was not a comprehensive and truly national one. The present scheme was not adequate in the matter of sickness benefit. While there was something to be said for the flat-rate system, it would be found that almost all the other countries had a higher rate of sickness benefit than we had. He was glad that the Minister of Health had relieved the minds of many members to a large extent by his statement about dental benefit. It was desirable that the Dental Joint Committee should be made a statutory body. Reference had been made as to the anxiety of the dental profession in regard to clinics. It was in the interests of insured persons and of the general public that they should have men and women of good professional status and with the corresponding sense of responsibility both in the dental and medical professions. The anxiety of the dental profession that the purely professional side should not be interfered with was quite reasonable, and in the public interest. Personally he would not approve of clinics being run by approved societies. He was glad to hear, therefore, that members of the dental profession would be represented on the management of the clinics. It was also very important from the public point of view, as well as from the point of view of the dentists, that there should be a free choice for patients, and he was glad that that privilege had been preserved. There was no doubt that if dental benefit were made an ordinary form of treatment and if full dental benefit were given to all insured persons the health of the members would be very considerably improved. There were many diseases caused by bad teeth. A great deal of the rheumatic diseases, about which so much was heard in industrial life, and which produced a very heavy sickness-rate with important economic complications, were really a form of chronic infection due to bad teeth. Therefore the expenditure on dental benefit was, in the long run, a very economical expenditure. The same applied to a lesser extent to the efficient treatment of the eyes. The supply of proper glasses to people who suffered from eye-strain was very important. It was important to emphasise the fact that although the Royal Commission had recommended these additional benefits and public opinion approved them, it was impossible to supply them without a restoration of the State grant which was given before the Economy Bill was passed into law. He very strongly urged the Minister of Health to put up a stronger fight with the Treasury to ensure that economy was not practised on the health of the people. If this Bill could not be sufficiently amended, he hoped another measure would soon be introduced, bringing in some of the more important provisions which the Royal Commission thought necessary. They must look forward to a time when the national health insurance service would be a real comprehensive service, developed not so much on curative lines as on preventive lines. Many of them looked forward to the time when the normal task of an insurance medical practitioner would not be so much that of curing people of as examining them periodically so that the earliest signs of disease could be detected. That comprehensive scheme could not be carried out until the extended benefits now so much needed were given. That, again, could not be brought about unless more money was brought into the scheme, which could only be done by a restoration of the proportion of the State grant which they had before the Economy Act was passed.

Increase in Sickness Benefit.

Sir H. CAUTLEY said that he viewed with great apprehension the steady increase in the amount paid out in sickness benefit all over the country. Unless some steps were taken to check this expenditure the whole scheme, sooner or later would be jeopardised. The extensive unemployment of the last few years might account for some of this increase, but not altogether, because it happened that in the rural societies where there had been no unemployment the same

mptoms existed. Probably it might be true that the crease of sickness benefit was greater in the large industrial ntres which had been hardly hit by unemployment. The heme for the administration of sickness benefit rested tirely with the doctors and the only control was the ppointment of a medical referee. He did not think the stem could be improved in that respect. The sole judge when an insured person required medical service and ould receive his certificate to get medical benefit must be e doctor, subject to the procedure relating to the medical feree. His suggestion to the Minister was that if the doctor as entrusted with this responsible work, his position ought be made as far as possible such that it did not conflict ith his duty. At present an insured person could, on a mere him, because it would annoy his panel doctor, at once say: I will change my panel doctor and go to someone else." iat system was, he was perfectly certain, working in this ay. He made no charge, either against insured persons or nel doctors, but if an insured person was feeling ill and he ought his doctor did not consider him ill enough if the ctor said "You are not bad enough to stop work, or to ve sick pay," then, in a fit of annoyance, he said "I will to a neighbouring doctor and go on his panel, because he easier." Let the House look at the position of a certifying ctor in such a case. He had, as his private patients rhaps, the man's wife and family, and if he lost that rticular patient he lost the whole family. The same thing ppened when a doctor had to certify the patient as being benefit. His (Sir H. Cautley's) suggestion was that no e should be entitled to change his doctor without giving, y, three or four weeks' notice. In such cases as those to nich he had referred, no doubt the fit of irritation would ve worn off in a day or two, the person would have gone ck to work feeling better, the whole thing would have blown er, and he would no longer have any desire to change his ctor. It had also been suggested to him that, in addition notice, reasons should be required, but he did not approve that. It would encroach on the free right of choice of ctor, in which he was a great believer. It would also an the setting up of some sort of tribunal to investigate e reasons. He firmly believed, however, that if some ecific period of notice had to be given there would be a very rked difference in the amount of sickness benefit paid out. the few societies with which he was directly concerned, had been found that in many cases where they had had to point a medical referee the patients had never gone to e medical referee at all, but had at once gone back to work. many other cases the medical referee had upset the rtificate that had been given. He was told the other day, ough he could not vouch for it, that in an instance in the ighbourhood of Bristol, where a referee was appointed to amine some 3000 cases, roughly speaking only 1000 came fore the referee. The mere fact of his appointment sent any of these people back to work and there the matter led. In many of the other cases the medical referee charged the certificates that had been given and said at the patients were fit for work. In only one-third of e cases, roughly speaking, was the decision of the doctor intained.

Lay Control

Dr. VERNON DAVIES said that the only way the opposition uld attack this Bill was by making some obscure reference a past raid on the insurance fund and by pointing out that e Minister of Health was very subservient to the Chancellor the Exchequer. If that were true, it increased his (Dr. vies's) admiration for the Chancellor of the Exchequer if had sufficient power to overawe or to guide the Minister Health, because among the medical profession in this ntry the Minister of Health was not by any means regarded a soft man. In fact they found him rather difficult to l with and perhaps sometimes a little autocratic. With ard to the question of the medical aid societies or clubs, ough he held no brief for the British Medical Association, imagined that the objection they had had for a long time s that the system adopted by these societies put medical n under lay control. For some years now he believed the sociation had taken certain steps to advise medical men to apply for these appointments. What happened in se cases was that the medical man became the servant of ay committee who had power to dismiss him.

Mr. MORGAN JONES: Just as in the case of the medical cer of health.

Dr. DAVIES said that when they applied the Insurance Act these medical aid societies they were in a different sition at once, because the essential thing under the surance Act was that the patient must have freedom of oice of doctor and he had not that choice in the case of clubs. That was one of the great objections to the sent system, but from all that he had heard he believed e standard of medical treatment which these medical aid sieties had been able to give had been very high. Although e societies had perhaps not met with the approval of ne members of the medical profession, the medical men who had served them had been of a high standard professionally and the members of these societies had probably received equally as good treatment as any other people in the land. Personally, if he interpreted the clause rightly, he believed that the existing medical aid societies would not be interfered with, but he hoped that no new societies would be allowed to be formed. He did not agree with all that had been said on the question of maternity mortality. It was a difficult thing. It was not entirely due to a lack of midwives, as some of his medical colleagues would suggest. There were a number of midwives in the country who would not undertake ordinary midwifery; they wanted to become nurses at welfare centres and objected to do the rough and tumble of going out every night in the week. That was one of the great difficulties. But the greatest difficulty of all was not the lack of medical attendance or sufficient nursing attendance; it was the conditions under which the confinement took place which was the danger at the present time. A great move towards improving the condition of affairs would be to move such patients into a home where they could be attended to by their own doctor and their own nurse. The question of dental clinics was important, and if these joint dental boards were to be set up he thought that the dentists should be represented. It was suggested that in the case of experimental dental clinics the approval of the dentists in the district was not essential. There was, however, a certain amount of danger in that. They might have one or two of the superior dentists in the district who would not touch this insurance work because the fees were not large enough, but they might go on the dental board and give the benefit of their advice. The men who were doing the actual work might in that case be overlooked, and there might be a difficulty in running the experimental clinic if the dentists of the district were not in cordial agreement. He hoped that the Minister would bear that point in mind. The essential thing in ophthalmic benefit was that the insured person should receive efficient and satisfactory advice and the scheme which the British Medical Association had suggested to supply a sufficient number of trained doctors who would work at fees suitable for approved societies was the best way to deal with the subject. Ophthalmic clinics would be run by qualified men who would give the best attendance and attention at the lowest price. He hoped that the Minister would not allow freedom of choice in that matter. He thought that something should be put in the Bill so that some benefit might be given to pregnant women at the time they needed it. Another omission from the Bill was in regard to the question of secrecy concerning venereal disease. The Minister knew that a guarantee or promise was made to panel practitioners that any information received in connexion with the treatment of venereal disease was to be held secret and inviolable. That guarantee or promise was made also to insured people, but now a judge in the High Court had decided that a panel practitioner could be compelled to disclose such information. The Minister ought to recognise this difficulty and something should be put into this Bill to meet it. He would ask the Minister to remember that there was a preventive as well as a curative side to national health insurance and personally he had doubts as to whether the most economic way of getting rid of their surpluses was by establishing dental and ophthalmic benefits. At the ages when those benefits applied people, as a rule, were capable of full work and could afford to pay the dentist and eye surgeon. More good would be done if instead of pushing their surpluses forward they pushed them backward, and did something to establish clinics for rheumatism where they could get at the children and the young people after school age when rheumatism was so dangerous, give sunshine treatment, and by other means help to establish a firm foundation of health at an early age, so that when they did enter into industrial life they would be fitted for it in every way.

Medical Institutions.

Mr. JOHN, referring to Clause 3, which dealt with the administration of medical benefit, said that if they read the clause they would conceive that though the hands were the hands of the Ministry of Health the voice was the voice of the British Medical Association. Clause 3 would abolish medical institutions. He (Mr. John) had been connected with medical institutions for the last 16 or 17 years, and he had never heard the name of "clubs" attached to them. It was not intended that the original Act should be a preventive or deterrent factor in connexion with the approval of medical institutions. This clause, however, would refuse the right of further existence to these medical institutions. One could not understand this refusal of further approval. No complaints had been brought against these institutions and they were subject to approval every year by the insurance committees. The operation of the clause would militate against the best interests of the members of these medical institutions and their families. Not only so, but the clause would be detrimental to the real object of providing the best

medical service and treatment for insured persons. One of the intentions of the National Health Insurance Act was to extend the scope of medical service and give benefit to a greater extent than had been possible in the past. One of the definitions in the regulations with regard to medical service was that the treatment which the practitioner was required to give to his patients comprised all proper and necessary medical services other than those involved in the application of special skill and experience of a degree or kind which general practitioners as a class were reasonably not expected to possess. If he understood that regulation correctly the real intention was to confine the panel patients to one doctor only, and to rationalise the work of the medical practitioner in the same way as was done by the fixing of the capitation figure. Although there was a free choice of doctors, once a man had chosen his doctor then he was entitled to the services of that doctor alone. The medical institutions were really getting down to the fundamentals and the objectives of the National Health Insurance Act itself on the lines of attempting to coördinate the whole of the medical services. The benefits not only included what was contained in the regulation to which he had referred, but the other benefits of the medical institutions. He (Mr. John) was a member of a medical institution called the Mid-Rhondda Medical Aid Society, and in addition to medical benefits contained in the regulations, such as proper aid and diagnosis of the complaint or disease, there were the use of the pathologists and second opinions with respect to expert specialist advice. Dr. Davies had been aguing for the right to increased benefits in the direction of pooling a certain proportion of funds for the payment of experts or specialists. That was not necessary with the medical institutions. The medical institutions at present provided expert and specialist advice and special treatment. They also provided all the laboratory facilities and dental and ophthalmic treatment and benefits. Again, professional nurses were provided by the medical institution, and not only electric treatment, but light treatment and massage.

Reply to the Debate.

Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health), replying to points raised in the debate, said that all the leaders of the approved societies up and down the country desired that the Bill should have a speedy passage to the Statute Book. But for the opposition of the approved societies of the country it would be perfectly possible to put into operation the scheme of specialist services without bringing any additional funds into the national insurance system at all, and no one had a right to say in that House that the specialist services were not being adopted on account of the Economy Act, or of any question of finance. The Royal Commission went very carefully into the question of specialist services and they stated that if the approved societies would come to an agreement and pool their funds that scheme could be put into immediate operation without any further addition whatever either by way of extra contributions or by way of State assistance. To carry out the suggestion that medical treatment should be provided for the dependents of insured persons would mean bringing in altogether, including the people who were already in the scheme, a total of not fewer than 31 million people, and the cost would be an additional £10,000,000 a year. He could assure the House that his right hon. friend would give very sympathetic consideration to any amendments moved in committee which were designed to improve the Bill.

The motion for the rejection of the Bill was rejected by 206 votes to 95 and the Bill was read a second time.

WEDNESDAY, APRIL 4TH.

Free Choice of Opticians.

Lieut.-Colonel MASON asked the Minister of Health whether, under the National Health Insurance Bill, the complete freedom of insured contributors to choose their own opticians would in any way be impeded.—Mr. CHAMBERLAIN replied: There is not in the National Health Insurance Bill, nor is there any intention to include in any regulations to be made under the Bill, any provision which would place an insured person in a less favourable position than hitherto with regard to the arrangements for obtaining ophthalmic benefit.

Removal of Children from Workhouses.

Mr. CONNOLLY asked the Minister of Health how many boards of guardians in England and Wales had complied with Article 4 of the Poor Law Institutions Order, 1913, which required the removal of all children above 3 years of age from the workhouse; and how many boards had not so complied.—Sir KINGSLEY WOOD replied: The number of boards of guardians who, for one reason or another, find themselves unable to comply completely with Article 4 of the Poor Law Institutions Order, 1913, may vary from day to day, but it would appear that, out of a total of 625 unions in England and Wales, there are 74 in which the Order is not regularly observed.

Pensioner and Specialist Medical Treatment.

Dr. SHIELS asked the Minister of Pensions if he was aware that pensioner 1/MM/2659, Charles Mackenzie, Musselburgh, applied for examination for an ear condition on Feb. 2nd last; that examination by the Ministry doctors was delayed till the 8th, when he was referred to his panel doctor for treatment; that his panel doctor said his case was one for an ear specialist, but that, on application to the Ministry for re-examination, this was refused on Feb. 25th and 29th; that on the 29th he was examined by the chief aural surgeon of Edinburgh Royal Infirmary, who advised and was proceeding to arrange for an early operation, but that owing to his being a pensioner the case had to be referred to the Ministry of Pensions who, on March 14th, wrote stating that the matter was still being considered; and would he explain the attitude of the Ministry in this case, in view of the serious possibilities of middle-ear disease from which this pensioner was suffering.—Lieut.-Colonel STANLEY (Parliamentary Secretary to the Ministry of Pensions) replied: This pensioner has received treatment from my department on many occasions during the past seven years, and operative treatment has frequently been recommended and offered to him. He has hitherto refused to undergo operation, and it has been found that no other form of specialist treatment was necessary. As he has now expressed his willingness to accept operative treatment, arrangements have been made to admit him to a Ministry hospital for the purpose.

Gas Fumes from Artificial Silk Works.

Mr. ROBERT YOUNG asked the Minister of Health whether any inquiries had been made by his department regarding the nature of the gas produced in and emitted into the atmosphere by artificial silk works; whether he was aware that this gas was said to be poisonous, and that the irritation produced by it was sufficient to cause pneumonia in young children; and that in some areas adjacent to such works doors and windows had to be kept closed because of the gas fumes.—Sir KINGSLEY WOOD replied: My right hon. friend understands there have been cases of emission of unpleasant gases from some works, but he is not aware of any injury to the health of residents in the neighbourhood of the works. My right hon. friend is, however, having further investigation made and, if the hon. Member has any information, I shall be glad if he will send it to my department.

Artificial Lighting Research.

Sir ROBERT THOMAS asked the President of the Board of Trade whether, in view of the importance of efficiency in artificial lighting, as affecting the eyesight of the nation, his department would be represented at the International Illumination Commission to be held in America in September next; and whether facilities would be given for representatives of the National Physical Laboratory and other public institutions, whom this question concerned, also to be present.—Sir PHILIP CUNLIFFE-LISTER replied: My department will not be represented at the conference mentioned, but His Majesty's Government will be represented through the Department of Scientific and Industrial Research. I understand that certain of the technical and industrial organisations concerned in the subject will also send representatives.

Dysentery among Native Prisoners in Solomon Islands.

Mr. WELLS asked the Secretary of State for the Colonies if he had any information with regard to the death of 11 natives imprisoned at Sinarango, in the Solomon Islands.—Capt. MARGESSON (Lord of the Treasury) replied: I regret to say that there has been an outbreak of dysentery among the prisoners, and that eight deaths have been reported. All possible measures have been taken by the senior medical officer to deal with the outbreak and the situation is said to be improving.

Insured Persons and Cost of Mileage and Drugs.

Sir ROBERT THOMAS asked the Minister of Health what was the yearly rate of contribution per head among persons insured under the National Health Insurance Act towards the cost of mileage and drugs in England and in Wales respectively.—Sir KINGSLEY WOOD replied: There is no provision for a specific contribution per head among insured persons towards the cost of mileage and drugs. The National Health Insurance Act, 1926, provides for an inclusive sum not exceeding 13*s.* a year per insured person, to be applied for the purpose of meeting the cost of medical benefit, the administration expenses of insurance committees, and any expenses incurred by the Minister in connexion with the administration of benefits. The amount available out of the 13*s.* for meeting the cost of mileage and drugs together is 3*s.* 3*d.* per insured person in each country. As, however, the total expenditure on mileage and drugs in Wales exceeded the amount available, the Act authorises payment out of the National Health Insurance Fund (England) to the Welsh

ational Health Insurance Fund for the purpose of meeting e excess expenditure.

Eye Disease in the Navy.

Sir ROBERT THOMAS asked the First Lord of the Admiralty nether any inquiry had been held into the fact that out a total, in 1926, of 1726 invalided from the Navy from l causes of injuries and disease, as many as 386 were on count of diseases of the eye.—Lieut.-Colonel HEADLAM arliamentary Secretary to the Admiralty) replied: An alysis of the 386 cases of men who were invalided in 1926 der the heading, "Diseases of the Eyes," shows that of is number 345 were due to congenital deformities of the e—namely, long sight, short sight, and astigmatism—ich brought the individual concerned below the visual ndard required in the rating held by him. Five men re invalided for defective colour vision. Of the remaining cases, three were due to injury, three to cataract, three iritis, and the others to chronic inflammatory or degene-tive conditions (ulcer, keratitis, retinitis, &c.). In w of the facts disclosed by this analysis I do not think at a special inquiry would serve any useful purpose. e hon. Member will appreciate that the detection of ent errors of vision is not easy, and that it is in conse-ence of the more frequent and rigorous examinations ich are now held after a man has joined the Service that se defects come to light.

THURSDAY, APRIL 5TH.

Replacement of Insanitary Welsh Schools.

Sir ROBERT THOMAS asked the President of the Board of ucation whether he was aware that 71 elementary schools Wales, accommodating an aggregate of 16,890 pupils, d been condemned as insanitary; and what action he posed to take to provide alternative accommodation thin reasonable distance of the children's homes.—rd EUSTACE PERCY replied: I am aware that there are present 71 elementary schools in Wales in category A the Black List. This does not, however, mean that all se schools are "insanitary" or that they have been ondemned." The Board are in constant communication h the local authorities and, in the case of voluntary ools, the school managers, in regard to individual cases, l, while the rate at which the schools can be replaced is ditioned by the particular circumstances of the individual as concerned, I think that, generally speaking, reasonable gress is being maintained.

Overcrowding of Amersham Infirmary.

Mr. SHEPHERD asked the Minister of Health whether his ention had been called to the report of the Amersham ard of Guardians with regard to the overcrowding of the rmary, in which it was stated that the conditions in the rds were very undesirable; that there was no possibility separating unpleasant and contagious cases from ordinary ients; that two cases at least amongst the men should in a separate small ward, one being a cancer case; that ase of phthisis in the women's ward was in a very infec-us state; that patients who were able to get up had to e their meals in close proximity to dying patients and ers who were helpless, and from the nature of their illness y unpleasant in their habits and conditions; and whether would immediately take steps to put an end to these ditions.—Sir KINGSLEY WOOD replied: My right hon. nd has received a copy of the report made by a com-tee of the Amersham Board of Guardians containing the tements to which reference is made in the question. e committee was one appointed by the guardians to sider the arrangements to be made to deal with the rcrowding at the infirmary. It is reported that arrange-nts were at once made to alleviate some of the matters rred to and others will receive the early consideration the newly elected board of guardians. My right hon. nd has no reason to suppose that further necessary ion will not be taken at the earliest possible date, and he poses to keep in touch with the matter.

ARTIFICIAL SUNLIGHT RESULTS.—In his report to annual general court of governors of the City of London spital for Diseases of the Heart and Lungs, Dr. H. lford Howell, tuberculosis officer for Hackney and Bethnal een, stated that artificial sunlight had not yielded the efits that had been expected. "Our experience," he d, "is that the majority of our cases have benefited little, in only one or two instances has definite improvement owed such treatment. Some cases, indeed, were worse. strong do well, but the weak do worse. Unfavourable ults are reported in febrile pulmonary tuberculosis, and s found that some patients, especially children, are stitutionally unfitted for treatment."

Correspondence.

"Audi alteram partem."

THE FOUNDLING SITE.

To the Editor of THE LANCET.

SIR,—I have read with much interest the annotation on this subject in your last issue. My interest may perhaps be judged to be biased, for without hesitation I admit that during the last three years I have exerted all my efforts toward winning the Foundling site for the Hospital for Sick Children, Great Ormond-street. Previously to this I visited in my spare time over 20 different country sites in order to obtain a suitable one for a country annexe. This, as is stated in your annotation, is now located at Tadworth. I have made the efforts with the conviction that, if these ends are achieved, in the future not only will English children greatly benefit, but the position of this country as a pioneer in the study of children's ailments will be strengthened and its international prestige in medicine thereby increased.

A necessary outcome of my views has been a very careful consideration of the principle which is lucidly summarised in your article in the sentence suggesting that Tadworth might in the future become the "centre of gravity" of the hospital. I should like to state my personal belief that it is not possible for a country annexe of a city hospital of the pioneer type to have in the true sense its centre of gravity in the country. I am sure that as years go by such a country annexe hospital will be of ever-increasing value, but there are certain insuperable objections to its becoming the centre of gravity or, as has often been expressed in other terms but not so well, that the city hospital will be only a clearing station. Among them are the following.

There will always be three classes of patients requiring the city hospital; the urgent cases medical and surgical, the obscure and undiagnosed cases, and those not necessarily obscure or urgent which are needed for special observation, research, and teaching. All physicians and surgeons, particularly those attached to children's hospitals, must, I believe, recognise that there are numerous cases acutely ill who could not be transferred without risk even 15 miles out of London. There will be some of these who unexpectedly develop an infectious disease and often an unexpected surgical crisis requiring highly skilled care. Special hospitals, naturally, are often confronted with most difficult cases, either beyond our powers of diagnosis or requiring for diagnosis very special methods of investigation. Useful and necessary laboratories can certainly be attached to the country hospital, but those required for special work and research must be in the city hospital, where they are in touch with every resource and can obtain special apparatus and so forth at the shortest notice.

Then again this hospital is a recognised teaching centre, and this entails providing for post- and under-graduate students' knowledge abreast of modern methods and also providing new methods, new ideas, and new facilities, if it is to be a pioneer institution. For this there must be at the city hospital clinical cases, scientific plant, and general organisation. It is asking too much to expect students to journey 30 miles for instruction. Research, an essential element in a pioneer hospital, must be in close and easy touch with all avenues of knowledge and must also have its chief home in the city hospital on account of the necessary equipment. These three elements—clinical and scientific facilities, teaching, and research—constitute, I venture to think, the centre of gravity of such a hospital.

There are other difficulties. Many parents (and I should be one) do not like their children with dangerous and obscure illnesses sent miles away at a moment's notice. Physicians and surgeons cannot, in the twinkling of an eye, manage journeys which

absorb two hours; yet it is essential for the vitality of a hospital that its honorary officers can carry out their duties. What may evolve when air transport is perfected I cannot foretell, but I believe that if now a pioneer special hospital in London, be it for children or any other object, were to shift its centre of gravity to the country two results would happen. First, the city hospital would lose its position in the medical world, and secondly, the country hospital would be gradually starved.

I am, Sir, yours faithfully,
F. JOHN POYNTON.

Devonshire-place, W., April 10th, 1928.

NASAL OBSTRUCTION AS A CAUSE OF DEAFNESS.

To the Editor of THE LANCET.

SIR,—I congratulate Dr. Macnaughton Jones upon the position he has taken up. For years I have been insisting upon the paramount importance of nasal obstruction in the production of many cases of catarrhal middle-ear deafness. But Dr. Macnaughton Jones goes too far in one direction and not far enough in another. On the one hand, I deprecate, and have long deprecated, the extensive and routine use of the cautery. It is a method which, on account of its scalding action (for, however much one tries to dry the nasal mucous membrane there is always too much moisture), is wider in effect than we can control. Consequently it frequently does more harm than good by the destruction of cilia in the area around its application. On the other hand, the effect of nasal abnormalities is not entirely one of obstruction; it is also one of *imperfect nasal drainage*, whereby acute catarrhal conditions are predisposed to, and chronic catarrhs set up and maintained. I have treated cases of early chronic catarrhal deafness years ago that recovered perfectly and have now forgotten that they were ever deaf—they were "caught in time," and dealt with seriously, not by temporising with washings or cautery. Others and similar cases who refused operation, either because they thought they knew better or because another otologist vetoed it, have progressed to chronic deafness and have returned in despair in later years. In some cases, again, the nasal catarrh either failed to improve after correction of the abnormality or there was no obvious cause for it in the nose. In such instances the underlying cause has proved to be a toxæmia, usually intestinal.

I am, Sir, yours faithfully,
MACLEOD YEARSLEY.

Wimpole-street, W., April 9th, 1928.

CONVALESCENT MEASLES SERUM.

To the Editor of THE LANCET.

SIR,—With reference to an attempt to control an epidemic of measles, published in your issue of March 17th (p. 548) I would like to support Dr. McClean's plea that convalescent measles serum should be made available to the public. I had occasion recently to try to procure such serum for a child to whom an attack of measles would have been dangerous; after trying various fever hospitals without success, I finally wired to a friend in Paris, who was able to procure it without difficulty at one of the children's hospitals, where it is collected from other hospitals, tested, and prepared for distribution. It would surely not be difficult for the Ministry of Health or the Metropolitan Asylums Board to organise a similar service in London and other towns; the coöperation of parents and ratepayers might be more readily secured by a little judicious propaganda through the press and wireless.

I am, Sir, yours faithfully,
C. L. C. BURNS.

St. Leonards-terrace, Chelsea, March 30th, 1928.

TONSILLECTOMY AND RHEUMATISM.

To the Editor of THE LANCET.

SIR,—Dr. K. Douglas Wilkinson and D. A. Ogilvie, in their paper on Rheumatism, Tonsils and Glands (THE LANCET, March 31st, p. 647) publish some interesting and valuable figures on this subject. They express doubt as to whether "the numbers under consideration are too small to allow of any definite conclusion." As the matter is one of much importance, and interests me personally as a member of the Liverpool Rheumatism Committee, I have worked out the probable errors of their figures which are included in the following two tables. Table II. will now read as follows:—

Present state.	Tonsillectomy, 35 cases. Number and percentage.	Non-tonsillectomy, 45 cases. Number and percentage.	Difference and probable error per cent.
(*a*) Heart normal..	15 (42·8)	12 (26·7)	16·1±7·3
(*b*) Heart damaged	8 (22·8)	12 (26·7)	3·9±6·7
(*c*) Cardiacs	9 (25·7)	15 (33·3)	7·6±7·0
(*d*) Dead	3 (8·7)	6 (13·3)	4·6±4·8
(*b*) } Together .. (*c*) }	17 (48·5)	27 (60·0)	11·5±7·5

Table IV. is better rearranged in the following manner:—

TABLE IV.—*Rheumatic Children.*

Heart condition.	Normal tonsils. Number and percentage.	Diseased tonsils. Number and percentage.	Difference and probable error of difference
Normal	20 (54 ±5·5)	6 (20±4·9)	34 ±7·4
Damaged	9 (24·3±4·7)	9 (30±5·6)	5·7±7·4
Diseased	8 (21·7±4·6)	15 (50±6·1)	28·3±7·6
Total	37 100·0	30 100·0	—

The examination of these tables shows that the only figure which is three times its probable error is that giving the difference in percentage of cases with normal hearts between those having healthy throats and those having tonsils and glands, the opposite being true of those with "diseased" hearts. This shows that the figures are sufficient to indicate that rheumatic persons with normal tonsils are definitely less likely to have developed heart disease than those with diseased tonsils. The figures published with regard to tonsillectomy, however, though suggestive, are hardly sufficient definitely to show the beneficial effect of the removal of the tonsils.—I am, Sir, yours faithfully,

C. O. STALLYBRASS,
Assistant Medical Officer of Health, Liverpool.

April 5th, 1928.

SIR DAVID FERRIER AND THE WEST RIDING MENTAL HOSPITAL.

To the Editor of THE LANCET.

SIR,—In your obituary notice of Sir David Ferrier you refer to an "invitation from Sir James Crichton-Browne, at the time superintendent of the West Riding Lunatic Asylum, to embody in the asylum reports the early results of his experiments." May I add the following quotation from "Experimental Researches in Cerebral Physiology and Pathology" (the West Riding Lunatic Asylum Medical Reports, vol. iii., 1873):—

I have to thank Dr. Crichton-Browne for kindly placing at my disposal the resources of the Pathological Laboratory of the West Riding Asylum, with a liberal supply of pigeons, fowls, guinea-pigs, rabbits, cats, and dogs for the purposes of my research.

This quotation indicates—what, to the West Riding Mental Hospital, Wakefield, is a fact of great

nportance—that the actual experimental work arried out by Sir David Ferrier on the localisation of nction in the brain was performed in the laboratories f this institution. This is the reason why the research as first published in our Medical Reports for 1873.

I am, Sir, yours faithfully,

J. SHAW BOLTON.

West Riding Mental Hospital, Wakefield, April 2nd, 1928.

NAVAL INVALIDING.

To the Editor of THE LANCET.

SIR,—In the course of a discussion in the House of ommons on invaliding from the Navy for tubercu-osis the official apologist admitted that the rules ight be too severe, and that the doctors were not iven sufficient latitude. Doctors on boards have to ork under the rules laid down for them, just as dges have to do under Acts of Parliament. What, hen, are the rules? They are given in part in a tter from the First Lord, which I quote from Hansard, "Before a disease can be accepted as ttributable to the Service it must be shown to have eveloped out of unusual conditions." But phosphorus ecrosis of the jaw surely developed out of what were hought usual conditions; was it then not attributable o phosphorus match-making? The conditions of attributability" may have to be changed, and trust the newly announced committee on attri-utability will consider this point, for there are any who think the conditions on board are at ault. Those conditions will come under review by he also newly announced board on hygienic con-itions, which should reduce the incidence of the isease. It has increased in the Navy in each of the ast two years (1924–25), of which we have been given omplete figures. Naval invalids have themselves o prove attributability; in the armies of the United tates and France invalids get disability pensions, nless the Service proves the disability to be the an's own fault. The naval invalid, when he has xhausted his savings, becomes a charge on the oor-law—in other words, the country must at last upport him. Why should he not be continuously aintained until he is cured by the Service to which e has given his best. That he is cast off by old riends and has to deal with a new and strange uthority increases by much the hardship of his nvalid condition.

I am, Sir, yours faithfully,

March 30th, 1928. NAVAL SURGEON.

TERRITORIAL ARMY.

Col. M. B. Ray, having attained the age limit, is retd. on ompletion of his tenure of appt. as A.D.M.S. 47th (2nd ond.) Div., and retains his rank with permission to wear ne prescribed uniform.

Lt.-Col. (Bt. Col.) L. D. Bailey from the Gen. List, .A.M.C., T.A., to be Col., and to be A.D.M.S. 47th (2nd ond.) Div.

Maj. A. E. Evans to be Lt.-Col. and to comd. the 140th Co. of Lond.) Field Amb.

Lts. P. J. Stokes, A. Swindale, and C. A. Cowie to be apts.

H. B. Trumper to be Lt.

ROYAL AIR FORCE.

Flight Lt. H. E. Hayes (Temp. Capt., Dental Surg., en. List) relinquishes his temp. comn. on relinquishment of is Army commission.

RESERVE OF AIR FORCE OFFICERS.

Honorary Flight Lt. W. G. Weston is promoted to the rank of Honorary Squadron Leader.

COLONIAL MEDICAL SERVICES.

H. U. Leembruggen, Provincial Surgeon, Ceylon, to be Medical Superintendent of the General Hospital, Colombo.

The following appointments have been made by the Secretary of State for the Colonies during the month of March: T. F. Anderson, Medical Officer, Kenya; R. V. Bowles, Medical Officer, Uganda; V. V. H. Hookai, Assistant Government Medical Officer, British Guiana; C. J. Austen, Medical Officer, Fiji; H. M. Boston, Medical Officer, West African Medical Staff, Gold Coast (Achimota College) and Capt. G. Winter, Medical Officer, West African Medical Staff.

MEDICINE AND THE LAW.

THE VITAMIN-CONTENT OF COD-LIVER OIL TABLETS.

ON April 4th the Salford stipendiary magistrate (Mr. Atkin) had before him a prosecution by the Salford Corporation against Messrs. Boots Cash Chemists (Lancashire), Limited, for the sale of cod-liver oil tablets not in conformity with the Food and Drugs Act. The case for the prosecution was that cod-liver oil tablets had been sold which were not of the nature demanded. A sample of "McCoy's Cod Liver Oil Extract Tablets" which had been sold to a Salford inspector had been examined by the city analyst, who reported that it contained among other ingredients 3·2 per cent. of oil characteristic of an alcoholic extract of cod-liver oil. Judged by the colour test this oily matter lacked vitamin A, one of the most valuable constituents of cod-liver oil, and apart from this, about 160 tablets would be necessary to obtain a minimum dose of cod-liver oil. Samples sent to the laboratories of the Pharmaceutical Society of Great Britain for biological tests were found to be lacking in vitamins A and D. The defending counsel, Mr. Whitehead, K.C., protested that he had had no instructions about vitamin D, and the question of adjournment was discussed. Eventually, however, witnesses were called. These included, for the prosecution, Dr. J. H. Burn, director of the Pharmacological Laboratories of the Pharmaceutical Society, and Miss Katharine Coward, D.Sc., who had actually performed the tests. These witnesses gave evidence as to the function of the laboratories, the guides available as to fair tests for tablets called cod-liver oil tablets, and the results of the actual animal experiments made. The laboratories had been established in order to enable manufacturers to have tests carried out which involved the use of animals; as director of the laboratories, Dr. Burn was responsible for all the work that was done. There were no official tests in this country for cod-liver oil, but one guide which was included in the United States Pharmacopœia was a test for vitamin A; while a second guide was found in the generally accepted view that cod-liver oil was able to cure rickets. The biological tests involved the use of rats prepared for experiment by having been fed on a diet free from vitamin A. Those rats, which received a daily dose of 0·01 g. of the tablets died within 14 days, whereas those which received a daily dose of 0·002 g. of cod-liver oil ceased to lose weight and resumed growth. A further test applied to see whether the tablets would cure rickets in rats proved negative, a similar dose of cod-liver oil curing the rickets in other rats of the same batch. Dr. Coward had had eight years of experience of tests for vitamin A and two and a half years' experience of tests for vitamin D. In answer to a question, Dr. Burn stated that in view of the results of the tests his opinion was that medicinally, as a substitute for cod-liver oil, the tablets were worthless.

The witness called for the defence was Mr. H. Droop-Richmond, chief analyst at the Boots laboratory in Nottingham, who stated that it was not until the present prosecution had been started that he handled the McCoy cod-liver oil tablets. He had never made

any tests as regards the absence of vitamin D. Messrs. Boots received certain essences from McCoy's and these were subsequently made up in tablet form from the formula of the McCoy firm who supplied the two main ingredients. That was all his firm had to do with their manufacture. The fact that the extract from the tablets did not give the colour test for vitamin A he attributed to the presence of certain other ingredients. He had not examined the particular sample submitted by the prosecution.

Counsel for the defence submitted that in the absence of any definite standard laid down by the British Pharmacopœia the prosecution had failed to show that what was sold was not of the nature, substance, and quality of the article demanded. He further submitted that his clients, not being concerned with the manufacture, were not prepared with any evidence regarding the animal tests. It was in fact a proprietary article, and the defendants were entitled to a dismissal. The magistrate inflicted a fine of £30 and 75 guineas costs. Leave was given to the defendants to appeal.

THE IRISH MILK-SUPPLY.

(FROM OUR OWN CORRESPONDENT.)

THE report of the Inter-Departmental Committee to Advise as to the Cleanliness and Wholesomeness of the Milk-supply—of which various more or less accurate forecasts had previously appeared—was published last week. The Committee was appointed in 1926 by the Minister for Local Government and Public Health. Among the members were four medical men—namely, Mr. T. Hennessy, T.D.; Mr. E. F. Stephenson, Chief Medical Adviser to the Department of Local Government and Public Health; Sir W. J. Thompson, formerly Registrar-General for Ireland; and Mr. M. J. Russell, Medical Officer of Health for the City of Dublin. Mr. P. F. Dolan, M.R.C.V.S., Chief Veterinary Inspector for the Dublin Corporation, was also a member. The Committee give a summary of the laws and regulations by which control of the production and sale of milk is carried on at present. They also survey the condition of the milk as it reaches the consumer. The opinion is expressed that the incidence of tuberculosis is comparatively low in Irish stocks, and that many of the small herds are free. The evidence quoted on this point hardly supports the conclusion. Of 204 samples of milk from suspected animals examined at the Veterinary Research Laboratory 9·31 per cent. were found positive. Again, 23·69 per cent. of the cows slaughtered at the Dublin Corporation abattoir in 1926 were found to be tuberculous; of the bullocks 6·52 per cent. were tuberculous, and of the heifers 5·59 per cent. It is estimated that there are at least 3000 animals giving tuberculous milk at present in the Irish Free State. In order to deal with this problem the Committee recommend that all cows should be inspected at least twice a year by a veterinary inspector. It is recognised that the complete eradication of tuberculosis within a short time is impracticable, on account of the cost and the shortage of milk that would result.

The "Accredited Herd System."

The Committee recommend the system of dealing with tuberculosis known as the "accredited herd system" as far as finances permit. Under this system stock-owners would apply to the Government to have their herds freed from tuberculosis, and would undertake to carry out directions in regard to housing, cleansing, disinfection, and purchase of new animals. The tuberculin test would be applied, and reactors removed and slaughtered, part compensation being paid. The herd should be periodically re-tested and reactors, if any, slaughtered. The Committee recommend that the compensation to be paid should be up to two-thirds of the market value of the animals slaughtered. The Committ also recommend a general improvement in existi cowsheds as regards light and ventilation, and more generous feeding of live-stock from bir onwards. The manufacture of tuberculin shou be controlled. The milk of cows suffering from a of the following conditions should not be used human food: acute or chronic mastitis, actinomyco of the udder, suppurative condition of the udd any tuberculous condition of the uterus, any sep condition of the uterus, retained placenta, any oth condition or affection of the cow, udder, or tea likely to convey disease. The Committee quo an interesting bit of evidence to support the view now coming to be widely held—that the bovi bacillus is not, as was held a few years ago, t main cause of non-pulmonary tuberculosis. A hi incidence of non-pulmonary tuberculosis in t Virginia District of County Cavan in 1926 attract attention, and the circumstances were examin with particular relation to the milk-supply. It w found that most of the cases occurred among childr who only drank goats' milk. The milk from eig cows supplying the remaining cases was examin bacteriologically with negative results, and no of the cows showed clinical evidence of tuberculos

Milk-borne Infections.

The Committee pass rather hastily over t question of milk-borne infections other than tub culosis. Some small outbreaks of milk-borne ente occurred in recent years, but were easily checke It is remarked that some medical witnesses we disposed to attribute the high death-rate fro diarrhœa and enteritis in children to contaminat milk, but the Committee think that, in Dublin any rate, other causes such as poverty, overcrowdin bad housing, and defective sanitary conditions ha to be considered. Attention is drawn to many wa in which milk becomes avoidably contaminat during production and transit to consumer, a simple remedies are suggested. Some urban autho ties have made a case for the right of access f purposes of inspection to sources of milk-supp situate outside their own administrative areas, much of the milk consumed in the towns come fro distant sources. The Committee see, howeve the possibility of a confused and uncoördinat multiplicity of inspection if such rights were grante It is hoped that the appointment of county medic officers of health will lead to adequate control.

The Committee received evidence to the effe that in some areas the children of the very po suffered from an insufficiency of milk. In the opini of one competent and experienced witness insu ciency of milk rather than its quality was the cau of ill-health among the poor children of Dublin.

Grading of Milk.

The Committee recommend the adoption in t Irish Free State of a system of grading of milk; a it is considered that two grades would meet t requirements of the country. These grades ar "Grade A—Tuberculin Tested," and "Grade A Milk of the latter grade should be bottled bef distribution; the herd should be submitted veterinary examination every three months; t bacterial count should not exceed 200,000 organis per c.cm., and there should be no coliform organis in 0·01 c.cm. This grade should be controlled a certified by the local authority. The higher grade "Grade A—Tuberculin Tested," should be from tuberculin-tested herd, and the count should not more than 100,000 per c.cm., with no coliform orga isms in 0·1 c.cm. The grade should be certified the Department of Local Government and Pub Health.

Among minor recommendations are that all m vendors should be licensed, that bottling of mi should only be done on registered premises, and th the sale of objectionable articles in the same sh as milk should be forbidden.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia was held on April 2nd, when Sir John Rose Bradford gave the annual presidential address and reviewed the work of the College. The number of Fellows, he said, was now 385 and of Members 916. He reported that portraits of Sir James Hope and Sir Percy Bassett-Smith had been received as gifts to the College, and gave an account of the life and works of the following Fellows who had died during the year: Ernest Henry Starling, Henry Cook, Sir Horatio Bryan Donkin, Charles Wilberforce Daniels, William Joseph Tyson, Amand Jules McConnel Routh, Alexander Blackhall Morison, Sir Percy William Bassett-Smith, Sir Dyce Duckworth, Sir Dawson Williams, Sir David Ferrier, Hugh James Moore Playfair, and Henry Lawrence McKisack.

Sir John Rose Bradford was re-elected President for the ensuing year.—The resignation of Sir Wilmot Herringham as representative of the College on the Senate of the University of London was accepted with much regret. It was decided not to fill the vacancy as the new Senate would shortly be appointed and the College would not be represented on it.—The President was appointed as delegate to the Commemoration of Harvey's Discovery by the Academy of Medicine in Paris.—Mr. V. R. J. De Boissière was declared to be no longer a Licentiate of the College.

The Diploma in Tropical Medicine and Hygiene was granted to the following 44 candidates from the London School of Hygiene and Tropical Medicine:—

C. R. Amies, Mary N. Andrews, R. E. Barrett, A. Bearblock, S. Bergsma, A. Dunlop, H. Fairbairn, Elisabeth Farra, H. A. Fawcett, M. M. Fikri, O. M. Francis, W. E. Giblin, H. K. Giffen, H. H. Gilbert, J. C. P. Grey, Alma B. Hardy, Eva Ho Tung, W. A. M. Jack, Dila Ram Jandial, B. M. Johns, R. S. Johnston, E. B. Jones, Margaret E. Lovett, Margaret M. McDowall, Amin Abd El Kaksood Magraby, Ram Chand Mahajan, M. V. Merchant, J. C. Milne, Jehangir Hormusji Oonvala, Thaliakattu Parukutti Ammal, J. R. Pierre, E. W. Reece, J. D. Reynolds, Enid A. Roberson, G. I. Shaw, T. A. Sherwin, G. A. Sloan, Hilda M. Smith, Abd El Mohsen Soliman, Grace M. L. Summerhayes, V. E. Whitman, N. J. Willans, C. H. Williams, and H. M. Willoughby.

UNIVERSITY OF DURHAM: FACULTY OF MEDICINE.—At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR M.B., B.S. DEGREES.

Pathology, Pharmacology, Public Health, &c.—*A. R. D. Pattison, †J. C. Arthur, †Abe Franklin, Sydney Adler, W. F. Cross, Kenneth Daniels, Andrew Davis, S. M. Garstein, C. M. Gillis, Katherine M. Girling, C. E. Goldberg, H. W. T. Hall, H. U. G. Harrison, J. G. Lawson, J. A. Lennox, D. C. Livingston, John Maddison, William Mair, J. H. Pool, J. K. H. Scott, J. W. M. Stevenson, J. B. Tilley, Howard Willcox, and Joseph Wolfe.

* First-class honours. † Second-class honours.

UROLOGICAL CONGRESS IN BERLIN.—A conference will be held of the Deutsche Gesellschaft für Urologie from Sept. 27th to 29th, 1928, at the Langenbeck-Virchow Haus, Berlin. The chief topics to be discussed are the pathology and treatment of malformation of the kidneys and ureters, and strictures of the urethra. Other subjects will include urology as a clinical specialty, hypertrophy of the prostate and diverticula of the bladder, and chronic non-specific ulcers of the bladder. The fiftieth anniversary of the discovery of the cystoscope will be celebrated at the opening session, when the work of Max Nitze will be recalled with due honour. Further particulars will be published later. Those who wish to take part in the conference are asked to communicate before July 15th with Dr. Arthur Lewin, Tauentzienstr. 13, Berlin W. 50.

MEDICAL CONFERENCE IN BRUSSELS.—The eighth session of the Journées Médicales will be held from April 21st to 25th in Brussels. Among the many foreigners giving communications are Eugène Gley and M.-P. Weil, of Paris, the former on the relations between the diverse activities of pluriglandular organs, and the latter on rheumatism at the menopause. Jean van der Hoeve (Leiden) will discuss affections of the eye in relation to general medicine, and L. M. Pautrier (Strasbourg) will speak on some aspects of epithelial cancer. Belgian speakers include Pierre Nolf and Jules Duesberg (Liège), Fernand L'Hollander (Louvain), Albert Dustin and Ernest Renause (Brussels), and I. Gunzburg and V. Possemiers (Antwerp). Operation theatres at various hospitals will be open to members of the conference and an exhibition and many social functions will be held. Further particulars and a detailed programme may be obtained from the general secretary, Dr. R. Beckers, 62 rue Froissart, Brussels.

UNIVERSITY OF OXFORD.—The electors have awarded the George Herbert Hunt Travelling Scholarship for 1928 to Mr. Thomas Holmes Sellors, B.M., who is at present casualty surgical officer at the Middlesex Hospital.

TERRITORIAL ARMY MEDICAL ASSOCIATION.—A reunion dinner open to all past and present Territorial medical officers, including à la suite officers, will take place under the auspices of this association on May 11th, at 7.30 P.M., at the Connaught Rooms, Great Queen-street, London, W.C., Major-General Sir Richard Luce, M.P., in the chair. For tickets apply to the Secretary at 36, Russell-square, W.C. 1.

A POST-GRADUATE course on tuberculosis will be held from May 21st to 26th at St. Blasien (Schwarzwald). Among others Profs. Aschoff, Eppinger, Küpferle, and Noeggerath, of Freiburg, will give lectures and Dr. A. Bacmeister, of St. Blasien, will deal with various points of interest, notably the management of tuberculosis by the practitioner and radiotherapy in tuberculosis. Further particulars may be had from Dr. Bacmeister.

TRANSFERENCE OF MANCHESTER TUBERCULOSIS DISPENSARY.—It is proposed to remove the Manchester Tuberculosis Dispensary from Hardman-street to the corner of Denmark-road and Oxford-road. The reasons given by the Public Health Committee are that the noise of traffic and other activities in the immediate neighbourhood is so great that it is impossible to examine the chests of patients with reasonable certainty of correct diagnosis other than at periods of diminished noise, and that the neighbourhood is permeated with exhaust fumes from motor vehicles. The cost of the new buildings, with their furniture and fittings, is estimated at £24,000, whereas the old premises are not expected to realise more than £4700.

THE LATE DR. I. A. DAVIDSON.—The death occurred on March 28th as the result of a street accident of Isaac Alexander Davidson, M.D., D.P.H., who was a graduate of the old Royal University of Ireland, and received his medical education in Queen's College, Belfast, and at Vienna. He was honorary surgeon to the Benn Ulster Eye, Ear, and Throat Hospital, ophthalmic surgeon to the Ulster Hospital for Women and Children, and ophthalmic specialist to the Belfast Educational Authority and the Ulster Brigade. He served in the war as captain in the Royal Army Medical Corps, and had duty in Belfast, Liverpool, and Seaforth. Dr. Davidson's personality was genial and attractive, whilst his professional ability was considerable. His early and unexpected death will be greatly deplored.

DONATIONS AND BEQUESTS.—Mr. Thomas Houldsworth Greenall, of Chorley, Lancs, left £5000 to the Chorley Hospital, and £1000 to the Chorley Nursing Association.—Sir Frederick Wise, J.P., D.L., M.P., of Holwell Court, Hatfield, Herts, left £500 to the Ilford Emergency Hospital and £500 for the benefit of poor persons in Ilford.—Mrs. Sarah Bunting, of Colwyn Bay, left £2000 to the Oldham Royal Infirmary to endow two beds to be known as the "John and Sarah Bunting Beds."—Mr. Ernest Shaw Redman, of Well Royd, Halifax, left £1000 to the Halifax Society for the Blind, £1000 to the District Nurses' Association, Halifax, £1000 to the Tradesmen's Benevolent Institution, £500 to Dr. Barnardo's Homes, and £500 to St. Dunstan's Hostel for the Blind.—Mr. William Dyson, of Pontefract, left the residue of his property, amounting to over £5000, "to the treasurer for the time being of Clayton Hospital and Wakefield General Dispensary, for the general purposes of the said institution."—Baron Glanusk, C.B., D.S.O., of Brecon, left £2000 to the Crickhowell Memorial Hospital and £1000 to the Brecon County Hospital.—Mr. William Thomas Smart, of East Haddon, Northants, left £1000 to King's College Hospital, London, to endow a "Harriet Smart Bed," and £1000 to Southampton General Hospital for a bed for parishioners of Hanslope.—The Ancient Order of Froth Blowers has set aside £1000 for the endowment of two cots at Guy's Hospital. At a cost of £500 each, a cot is to be endowed at each of the following institutions: Royal Alexandra Hospital for Sick Children, Brighton; Queen Mary's Hospital for the East End; Charing Cross Hospital; the Prince of Wales's General Hospital, Tottenham; and the British Hospital for Mothers and Babies, Woolwich.—Mr. Ralph Lees, of Hollinwood and Oldham, engineer, left £2500 to the Oldham Royal Infirmary to endow two "Ralph Lees" beds, £1000 each to the Manchester Royal Infirmary, the St. Mary's Group of Hospitals, Manchester; the Cancer Hospital, Manchester; the Oldham Bluecoat School, St. Dunstan's Hostel for Blinded Sailors and Soldiers, Dr. Barnardo's Home, the Cancer Hospital, London; and "The Children's Hospital, London"; and £500 each to St. Bartholomew's Hospital, London; Ancoats Hospital, Manchester; the Manchester Eye Hospital, the Salford Royal Hospital, Henshaw's Blind Asylum, Manchester; and the Oldham Institute for the Blind.

NOTTINGHAM HOSPITAL SATURDAY FUND.—Last year this Fund collected £27,739, of which £25,297 was allotted to the General Hospital.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—This hospital has moved to the new building, Broad-street, High Holborn, W.C.2, and was open to patients last Tuesday (telephone, Regent 1457/8).

GENERAL LYING-IN HOSPITAL.—A matinée will be held at Daly's Theatre, London, on Tuesday, May 22nd, in aid of the extension fund of this hospital. Tickets may be had from the chairman of the appeal committee at the hospital, York-road, Lambeth, S.E. 1.

WOOLWICH WAR MEMORIAL HOSPITAL.—The following additional appointments have been made to the staff of the Woolwich War Memorial Hospital: Obstetric surgeon, Mr. Harold Taylor; senior anæsthetist, Dr. F. P. de Caux; anæsthetists, Dr. Moore Smith and Dr. A. D. Dyson. Dr. William Cowie and Dr. Moore Smith have been elected to the medical committee of the hospital to represent the interests of the practitioners in the Woolwich district.

MEDICAL PROFESSION AND DENTISTRY.—In the debate on the Dentists Bill in the Senate of the Irish Free State a final attempt was made to complete the separation between the medical and dental professions which the Bill already carries far. An amendment was proposed by Sir E. C. Bigger, a medical senator, to remove the control of dental education from the Medical Council to the Dental Board. It was strongly opposed by Mr. McGilligan, the Minister in charge of the Bill, who declared that the amendment was not in accordance with the wishes of either the medical or the dental professions, and was defeated.

BIRMINGHAM HOSPITALS.—The 148th annual report of the Birmingham General Hospital states that delay in finding additional accommodation makes the work of the hospital more and more difficult. Over 3000 urgent cases had to be sent on to other institutions last year and the number of street accidents not only makes serious inroads upon the available beds but adds to the work of special departments, "all of which are trying to meet what is required of them under almost impossible conditions."—At the annual meeting of the Birmingham and Midland Hospital for Skin and Urinary Diseases, Dr. David Rowlands pointed out that when he first knew the hospital venereal disease was responsible for one-quarter of the cases; now it accounted for only 4 per cent. Another speaker said that the majority of the cases now seen are of a kind not yielding readily to treatment.

BRIGHTON HOSPITALS.—The annual meetings of the governors of the hospitals at Brighton were recently brought to a close. A year of remarkable progress was reported at each, but in the majority of cases the financial side gives cause for concern. At the largest of the institutions—the Royal Sussex County Hospital—the casualty cases during 1927 rose from 4914 to 6304, while the total number of cases seen in the casualty department increased from 7852 in 1926 to 9616. The great increase in casualties was described as appalling, and arising in the main as they did from motor traffic, the question arose whether hospitals should not be entitled to compensation for treatment as a matter of routine, and not merely as an act of grace, from either the insurance companies or the Road Fund. The governors considered that some common action should be taken.—The general fund of the Royal Alexandra Hospital for Sick Children was overdrawn at the end of 1927 by £2400, but the governors hoped to see the sum liquidated this year in connexion with the diamond jubilee of the institution. There was also the serious additional financial burden arising from the operation of the new rating assessment under the Rating and Valuation Act. Hitherto the hospital had been called upon to pay rates amounting to about £15 per annum; the new figure was nearly £600. The new wing which was being erected as a memorial to Queen Alexandra would, it was stated, bring the number of beds to 100.—The Sussex Maternity and Women's Hospital recorded the opening of a home for nurses towards the capital expenditure of which the Minister of Health, on being appealed to, had made a grant of £40 for 20 years.—The Sussex Throat and Ear Hospital has entered upon its jubilee year. Only £2000 has been raised of the £6000 required for the contemplated extension scheme, and until that sum is doubled the governors cannot see their way to proceed.—The Sussex Eye Hospital is to be modernised; it has been decided to spend £10,000 in bringing the old premises up to date.—The new wing opened at the New Sussex Hospital in Windlesham-gardens, Brighton, will increase the number of in-patient beds from 30 to 50, and provide improved accommodation for the staff. The hospital is one of four only in the kingdom staffed entirely by women—the porter is the only man.

DONCASTER INFIRMARY EXTENSION.—The committee have decided to begin building a unit of 120 beds to cost £120,000, and to be known as the Queen Alexandra Memorial Wards, as the first wing of their new £300,000 hospital.

WORTHING HOSPITAL.—Nearly £20,000 has recently been spent on extension of this hospital, and it is hoped that a new women's ward and X ray department will be opened next year to celebrate the centenary. Last year's working was satisfactory, the finances showing a small credit balance.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, April 17th.—5.30 P.M., GENERAL MEETING of FELLOWS. Ballot for election to the Fellowship.

THURSDAY.—8 P.M., NEUROLOGY. Clinical Meeting at West End Hospital for Diseases of the Nervous System, Out-patients' Department, Welbeck-street, W.

FRIDAY.—8 P.M., OBSTETRICS. Specimens: Mr. C. J. Read: (1) Teratomatous Ovarian Tumour with Torsion of the Pedicle. (2) Columnar Carcinoma of Fundus Uteri with Metaplastic Change to Epithelioma in the Lower Part of the Growth. Papers: Mr. R. J. Paramore: Eclampsia and its Treatment: An Experience with Spinal Anæsthesia in One Case. Prof. W. Blair Bell: The Malignant Functions of the Chorionic Epithelium.

HARVEIAN SOCIETY OF LONDON.

THURSDAY, April 19th.—8.30 P.M. (in the Paddington Town Hall), Discussion on the Treatment of Ulcerative Colitis from Medical and Surgical Points of View, to be opened by Dr. H. Letheby Tidy, followed by Dr. L. E. C. Norbury, Dr. E. Bellingham Smith, and Mr. C. P. G. Wakeley.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, April 20th.—2.30 P.M. (in the Guildhall, Bath): Discussion on Causes of the Decline in Tuberculous Mortality, to be opened by Sir Robert Philip, Dr. W. M. Willoughby, Prof. E. L. Collis, and Prof. Major Greenwood.

LONDON CLINICAL SOCIETY.

THURSDAY, April 19th.—8.30 P.M., Infections of the Tonsils and their Sequelæ.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

BELGRAVE HOSPITAL FOR CHILDREN, Clapham-road, S.W.

WEDNESDAY, April 18th.—4.30 P.M., Dr. H. Oddy: Clinical Meeting.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 20th.—4 P.M., Mr. Harold Kisch: Multiple Nasal Sinusitis.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 17th.—4.15 P.M., Dr. W. F. Shaw: Fallacies of Forceps.

FRIDAY.—4.15 P.M., Dr. T. H. Oliver: Demonstration of Medical Cases.

Appointments.

COOK, EVA D., M.B., B.S., has been appointed House Surgeon to the New Sussex Hospital for Women and Children, Brighton.

HUNT, ELIZABETH, M.D., Ch.B. Liverp., Honorary Senior Medical Officer, Liverpool Hospital for Cancer and Skin Diseases.

PARRY, R. H., M.B., B.S. Lond., D.P.H., Medical Officer of Health for Bristol.

Westminster Hospital: WAINWRIGHT, J. H., L.R.C.P. Lond., M.R.C.S., and MCGRATH, A. M., L.R.C.P. Lond., M.R.C.S., Resident House Physicians; MORGAN, T. W., L.R.C.P. Lond., M.R.C.S., Resident House Surgeon; GREENE, C. J., L.R.C.P. Lond., M.R.C.S., Resident Obstetric Assistant.

Certifying Surgeons under the Factory and Workshop Acts: HOWIE, T. W., M.B., Ch.B. Glasg. (Rothesay); TUNIS, W. L., M.D., Ch.B. St. And., D.P.H. (Newburgh, Fife); and WALTER, A. G., L.R.C.P. Lond., M.R.C.S. (Wallingford).

Vacancies.

For further information refer to the advertisement columns.

Alton, Hants, Lord Mayor Treloar Cripples' Hospital and College.—Second Asst. Res. M.O. £300.

Barrow-in-Furness, North Lonsdale Hospital.—H.S. £130.

Beit Memorial Fellowships for Medical Research, 35, Clarges-street, W.—Junior Fellows. £400.

Birmingham and Midland Ear and Throat Hospital.—Asst. Surg. O. £200.

Birmingham, Dudley-road Hospital.—H.S. At rate of £200.

Birmingham, Highbury and Uffculme Hospitals.—Jun. Res. M.O. £300.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. £120. Also Out-patients' Officer to Ophth. Dept. £65.

Bradford Royal Infirmary.—Two H.S.'s and H.P. Each £150.

Bury and District Joint Hospital Board.—Res. Asst. to Med. Supt. £400.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Chester Royal Infirmary.—Hon. Asst. Anæsthetist.

City of London Hospital for Diseases of Heart and Lungs, Victoria Park, E.—M.O. At rate of £100.

Dreadnought Hospital, Greenwich.—Anæsthetist. 50 guineas. Also Surgeon in charge of Out-patients.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. and Whole-time Cas. O. Each at rate of £125.

Exminster, Devon Mental Hospital.—Jun. Asst. M.O. £300.

Harrington General Dispensary, Holborn-circus, E.C.—Hon. Phys.

Glasgow Royal Infirmary.—Deputy Med. Supt. and Sen. Med. Resident. £200.

Gloucestershire Royal Infirmary.—Asst. H.S. At rate of £120.

Guildford Union Institution, Warren-road.—Res. M.O. £500.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Hospital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.

Huddersfield Royal Infirmary.—H.S. £150.

Laboratories of Pathology and Public Health, 6, Harley-street, W.—Asst. Pathologist. £500.

Leeds, St. James's Hospital.—H.P. and S. £200.

Liverpool Eye and Ear Infirmary.—Third Hon. Anæsthetist.

London Homœopathic Hospital, Great Ormond-street, W.C.—Phys.

London Hospital, E.—First Asst. and Reg. to one of the five Surg. Firms. £300.

Manchester Royal Infirmary.—Dickinson Research Travelling Scholarship in Medicine. £300. Also Dickinson Surgery Scholarship. £75. Jun. H.S. £100.

Nottingham General Dispensary.—Res. Surg. £250.

Portsmouth, St. Mary's Infirmary.—First Asst. Res. M.O. £350.

Redruth, W. Cornwall Miners' and Women's Hosp.—Rsdiographer.

Rochester, St. Bartholomew's Hospital.—Third Res. M.O. At rate of £175.

Rotherham Hospital.—H.P. £180.

Royal Chest Hospital, City-road, E.C.—Res. M.O. At rate of £150.

Royal College of Surgeons of England.—Examiners.

Royal Naval Medical Service.—Surg. Lieutenants. £453.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.

St. John's Hospital for Diseases of Skin, Leicester-square, W.C.—Hon. Asst. Phys.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Registrar. £100.

Sheffield Royal Hospital.—Res. Anæsthetist. At rate of £80.

West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Registrar. £200.

Windsor, King Edward VII. Hosp.—Jun. H.S. At rate of £100.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Finedon (Northampton), Wivenhoe (Essex), and Accrington (Lancashire).

The Home Secretary gives notice that Mr. M. W. B. Bulman, M.B., F.R.C.S., has resigned his post as one of the Medical Referees under the Workmen's Compensation Act, 1925, for the Districts of the Aylsham, Downham Market, East Dereham, Fakenham, Holt, King's Lynn, North Walsham, Norwich, Swaffam, Thetford, and Wymondham County Courts (Circuit No. 32). It is proposed to appoint a surgeon to fill the vacancy. Applications from surgeons should be addressed to the Private Secretary, Home Office, London, S.W. 1, and should reach him not later than April 25th, 1928.

Births, Marriages, and Deaths.

BIRTHS.

HATTERSLEY.—On March 31st, at Aldershot, the wife of Major S. M. Hattersley, R.A.M.C., of a son.

STUBBS.—On March 30th, the wife of Major J. W. C. Stubbs, R.A.M.C., of a son.

WELLS.—On April 2nd, at Belvedere House, Danbury, Chelmsford, the wife of J. Pascoe Wells, M.B., of a daughter.

DEATHS.

MACLEAN.—On April 2nd, at Eastbourne, Kenneth Maclean F.R.C.S., L.R.C.P., late of Holloway, N.

PATERSON.—On April 5th, Neil Munro Paterson, L.D.S., D.M.D., aged 27 years.

TRIBE.—On March 31st, at a nursing home in Newport, Alfred Gladstone Tribe, M.R.C.S.,L.R.C.P., of Usk, Monmouthshire.

WIGHAM.—On April 5th, at Dean Park-road, Bournemouth, Dr. John Harper Wigham, aged 65.

N.B.—*A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.*

Notes, Comments, and Abstracts.

A CASE OF PELLAGRA.

Dr. Burr Ferguson, of the United States public health service, who formerly worked for some time in the municipal laboratory at Southampton, narrates in the February issue of *Clinical Medicine and Surgery* an interesting case of the successful administration of succinimide of mercury, where the patient appeared at first inspection to be dying of pellagra. She had the typical symmetrical lesions on hands and forearms, and mental and nervous symptoms were pronounced. The physical condition had improved in a nursing home, but a mental consultant had given it as his opinion that such days as remained to the patient would have to be spent in the lunatic asylum. An injection of 0·05 g. of succinimide of mercury was given by Dr. Ferguson, who reports that thereupon symptoms were arrested and convalescence ensued.

NEW PREPARATIONS.

Calcium "Sandoz."—This salt, which is prepared by the Sandoz Chemical Works, 5, Wigmore-street, W., is a combination of calcium and glucose, for which it is claimed that whether given by the mouth or by intramuscular or intravenous injection good results can be obtained in the many conditions where calcium is indicated: the manufacturers mention a large range of these indications, some of which will appear more clear to medical practitioners than others. The powder is supplied in boxes of 2, 4, and 16 oz., and it is recommended that it should be taken between meals in tea, coffee, milk, or fruit juice sweetened according to preference, the dose for adults being 1 to 2 teaspoonfuls three times daily, half that dose sufficing for children. For injection the salt is supplied in boxes of 1, 5, and 20 ampoules, each of which contains 10 c.cm. of a 10 per cent. sterile solution of gluconate of calcium, and one ampoule is recommended for injection every two or three days. A note in the *Deutsche Med. Wochenschrift* suggests that Calcium Sandoz has proved an effective remedy in asthma and other conditions of an asthmatic character.

Hydnocarpus Wightiana Oil.—We have received a specimen of this oil prepared by the Ernakulam Trading Co., Ltd., Ernakulam, S. India. It is employed in the treatment of leprosy as a substitute for chaulmoogra oil, from which it differs in colour, odour, and specific gravity, but the preparation receives a practical testimonial from Dr. Robert G. Cochrane, who was responsible for the final report on medical work for the mission to lepers in India, and who has found the oil "one of the cheapest and best drugs for the treatment of leprosy."

Tessol is prepared at the laboratories of Messrs. E. T. Pearson and Co., Ltd., 35, Gordon-square, London, and is a combination of essential oils designed for use in gastro-intestinal disorders. As is well known (THE LANCET, 1926, ii., 721), preparations of the essential oils have been employed with success in the pre-collapse stage in cholera, so that the manufacturers have support for their claims that they are providing a scientific remedy of proved use in certain conditions. The formula is not given, but a combination of such well-known drugs as ol. anisi, ol. cajaput, and ol. juniper has been found in the evacuation stage of cholera to act as a carminative, stimulant, and astringent, and the same properties are claimed for tessol. The correct dose for children and adults is suggested by the manufacturers, who state that it contains no opiates.

MEDICAL EXPERIENCE OF A BIRTH CONTROL CLINIC.

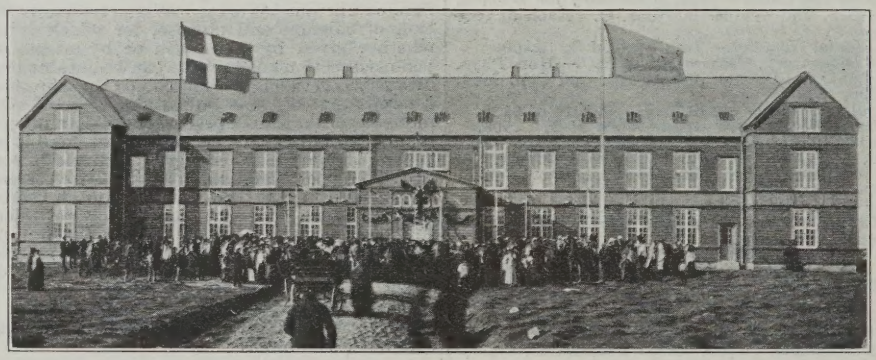
IN our issue of Dec. 31st, 1927 (p. 1400), some comments were made upon the medical aspects of birth control which arose from the annual report of the Walworth centre of the Society for the Provision of Birth Control Clinics. In the third annual report of the North Kensington branch of this Society [1] these medical aspects have been fully dealt with in a supplement written especially for medical readers. It is here argued that the only circumstances which justify the view that the practice of contraception causes physical harm are those created by an absence of medical supervision. In the first place there is nothing to prevent a woman from buying an ill-fitting pessary in a shop. Experience has shown that certain occlusive pessaries—particularly the so-called Dutch pessaries—require careful fitting to be effective. There are certain circumstances—notably when there is a profuse cervical discharge—when the use of an occlusive pessary is contraindicated. In the absence of medical supervision there is nothing to prevent such a condition being overlooked. In the second place it

[1] Obtainable from the Secretary, 12, Telford-road, Ladbroke-grove, London, W.

is always open to the couple desiring to limit their family to practise coitus interruptus, the harmfulness of which is fairly generally acknowledged. Statistics now in preparation indicate that this method of birth control is very widespread. It is further claimed in this supplement that the activities of the doctors at these clinics, by whom a full pelvic examination is made of each case, result in the detection of early disease rather than in the causation of disease. A list of cases in which genital disease was discovered in the course of the routine pelvic examination is given. The women were referred to a hospital. Lastly, the attitude of the Ministry of Health is outlined and stress is laid on the fact that any doctor is at liberty to refer a woman patient at any time for advice to a birth control centre. This supplement should be of value to all interested in the medical aspects of birth control.

LEPROSY IN ICELAND.

THE work of Prof. Saemundur Bjarnhjethinsson in the cure and eradication of leprosy is probably less well known than it deserves to be. It was in 1898 that coördinated methods were definitely adopted in Iceland for combating the disease. The former seat of the Bishop at Laugarnes was acquired and, having been converted into a hospital, was presented to Iceland by the Oddfellows of Denmark. At that time there were 250 cases in the island, whereas to-day the total is 44; thus in 30 years the number has been reduced by a clear four-fifths. Since the foundation of the hospital none of the workers there has contracted the disease. The risk of infection is regarded as slight, and the law does not compel the incarceration of all patients. Ten lepers on the island, while enjoying comparative freedom, are now almost cured; the remaining 34, more serious cases, are confined to the hospital, of which we publish a photograph. The curative methods adopted may be summarised under the headings: cleanliness, nourishing food, chaulmoogra oil and other esters, and a considerable proportion of the patients are said to be progressing very favourably. Prof. Bjarnhjethinsson's hope, which appears in no way unreasonable, is that the country will be entirely free from the disease in about 40 years. He states that the only Government which has deemed it worth while to make inquiry concerning leprosy in Iceland has, up to the present, been that of the Philippines.



Hospital for lepers in Iceland.

A MEDICAL FISHERMAN.

Dr. J. Brunton Blaikie, who writes pleasantly and modestly of his fishing experiences in Great Britain and in Norway,[1] will find appreciative readers among those many medical men who share his hobby. He gives enough technical details of his methods and preferences to help the novice, while those who are themselves experts will enjoy the racy accounts of experiences common to most fishermen. Dr. Blaikie recommends fishing as the sport most certain to give rest and refreshment; but adds that one who fishes as he would take a medicine is hardly less despicable than one who plays bridge in order to make money. The fact that many of his companions are well known in the profession adds to the interest of his book.

A USEFUL POCKET FLASK.

Messrs. J. and F. Martell have placed on the market for the convenience of travellers a neat little flask measuring approximately $4\frac{1}{2} \times 2\frac{1}{2} \times 1$ inches, and shaped to fit the pocket. The "cork" consists of a patent cap which can be instantly removed or replaced and which securely seals the mouth of the flask, while an aluminium drinking-cup slides over the lower half of the container, thus affording protection against breakage. The flasks contain the Three Star Brandy distilled by the firm and they can be obtained at most licensed houses as well as on channel steamers and air liners.

[1] I Go a-Fishing, by J. Brunton Blaikie, M.D. London: Edward Arnold. 1928. Pp. 224. 10*s*. 6*d*.

A SYMPATHETIC PSYCHONEUROSIS.

A LAY correspondent inquires whether we know of other cases of husbands who suffer in sympathy with their wives at the monthly periods. His own experience is as follows:—

I am 37 years old, was married in 1923, but my present symptoms did not begin until I returned from the war. Now at each of my wife's recurring monthly flows I have aches in the back, head, and legs, especially the last, a feeling as if I were in the first stage of a bad cold, but no cold develops (it was, by the way, this non-sequence which first pointed me to the actual cause). I do not keep count of the months, but I am aware, without my wife informing me, when her period comes round, and, were we a thousand miles apart, I should know just the same.

The case is evidently a psychoneurosis, and, if rare, is at all events not without precedent. We know of a psychical homosexual who claimed to suffer the throes of menstruation. Another man who had been upset at the birth of his first and only child, and dreaded his wife becoming pregnant again, had hysterical fits; on coming round from one of these he declared that he had gone through the pains of childbirth. Related to this subject is the well-known custom of the *couvade*, in which, in certain tribes the husband goes to bed when a child is born to his wife, and is treated as he had done the whole thing himself. There is a belief in some parts of this country that when a wife is pregnant the husband is subject to toothache. Readers will recall a recent sketch in *Punch* of a young husband in obvious distress being reassured by the family accoucheur in the following words: *Young husband:* It will kill me. *Doctor:* I've brought thousands of babies into the world and never lost a father yet.

FEES FOR THE EXAMINATION OF CASUALS.

"Acacia" writes: Circular 880 of the Ministry of Health has extended to June 30th the arrangements for the detection of small-pox among casuals, and it becomes now more than ever necessary to ascertain what remuneration the different boards of guardians will be paying, and to try to get a uniform scale. "Vagrant's" suggestion (in your issue of March 17th) of 1*s*. per casual inspected seems fair. I hope some official lead will be given, otherwise one's claims may be shelved.

SUPERSTITION IN SUSSEX.

To the Editor of THE LANCET.

SIR,—The following is pretty good for enlightened England in this year of grace 1928: We have a cook-general, a Sussex woman, aged 40, who has been a cook for many years. Yesterday my wife asked her to separate the giblets and liver from a trussed fowl before roasting. She hesitated and the request being repeated, gaped and said, "Oh, please 'm I couldn't mum! Not to-day mum." When asked "What on earth do you mean?" she explained, "Oh, please 'm they say you mustn't touch raw meat when you're—*you know mum*"! I am familiar with the dairywoman's tradition of the noxious effects of menstruation on milk and cream, and with Moses' instructions in Leviticus, but this selection of meat for taboo is new to me.

I am, Sir, yours faithfully,

Emsworth, Hants, March 27th. H. CAMERON KIDD.

*** We recorded many years ago the belief of country women in Wessex and Worcestershire that they ought not when menstruating, to handle raw meat for fear of spoiling it. —ED. L.

THE full name of the new antiseptic solution put on the market by the British Drug Houses, Ltd., is Caprokol Antiseptic Solution S.T. 37.

IN the advertisement for Ostelin that appeared in our last issue it should have been stated that the figures at the top of each column of the chart represent units of vitamin A contained in 1 gramme of the substance tested.

An Address

[ABRIDGED]

ON

THE MEDICAL PERSPECTIVE OF MULTIPLE EXTRACTIONS

AND OTHER MAJOR DENTAL OPERATIONS.

Delivered to Post-graduates at the Royal Dental Hospital on March 28th, 1928,

BY HARVEY HILLIARD, C.B.E., M.D. ZÜRICH, M.R.C.S. ENG., D.P.H.,

SENIOR ANÆSTHETIST TO THE HOSPITAL.

THE extraction of teeth is so painful, and is sometimes accompanied by so much shock, that before the discovery of anæsthesia it was never resorted to except for the relief of pain—or as a means of raising revenue, if the history books describing the habits of the earliest English kings are to be believed. In consequence, oral sepsis was rampant, the general health suffered, people did not live so long, and the death-rate was much higher than it is now.

Even after the introduction of nitrous oxide gas, for many years no one would have a tooth extracted unless it were aching, or visit the dentist except for the relief of pain. This was because, in the early days, the gas was impure and was administered badly and with very little knowledge of its physiological action and after-effects; it made many people feel so ill that they preferred to have a tooth out without any anæsthetic at all. They avoided visiting the dentist, except for the relief of pain, because it was not then generally known that decaying teeth poison the whole system and undermine the general health. Now we know better; people take more care of their teeth and, I am told, the hygiene of the mouth is taught in the public elementary schools—in America.

Even to-day, however, cases of extreme oral sepsis are an everyday occurrence and extensive operations have to be performed for the removal of teeth too septic to be saved. Unhappily, the present practice, all too commonly, is to perform these severe operations at the dentist's surgery, after which the patient has to take a journey home, shocked, bleeding and nauseated; not only this, but if the operation has not been completed and has to be done "piecemeal" on successive occasions, he is depressed both mentally and physically in anticipation of having to go through the ordeal again. Further, he may suffer symptoms of severe illness, with signs of general toxæmia, as a result of absorbing a large dose of toxin from the sockets of the teeth which have been removed, since these sockets become heavily infected from the teeth which remain.

AN EVIL TRADITION.

Why, then, are these operations usually performed at the dentist's surgery rather than at the patient's own home? It is because of the tradition. But, apart from the "odontophobia," if I may coin a word, or the "dental retention complex" (as the psychoanalysts might say) how has this tradition arisen?

It has become the custom for the patient to visit the dentist, rather than for the dentist to visit the patient, because it used to be very rare for more than one tooth to be removed at a time and the extraction of a single tooth was considered a trivial operation—at least by the dentist! It was more expedient and saved time to proceed in this manner, and there was the advantage of operating in a special dental chair, in a good light, and where all the necessary instruments are at hand. With the introduction of anæsthesia extractions became more extensive, but still the patient had to go to the dentist; because when first introduced the nitrous oxide gas was prepared only at the dentist's house, being stored in gasometers ready for use when required. The introduction of compressed and liquefied nitrous oxide in steel cylinders, thus making it readily portable, should have changed the procedure in the cases in which two or three extractions were necessary, but the tradition had arisen and traditions die hard; also, apparently, it did not occur to anyone that things might be done more comfortably and with less risk for the patient.

More recently still, the nasal method of administering nitrous oxide (introduced by Mr. Frank Coleman and myself in 1898) whereby anæsthesia can be indefinitely prolonged, has led to very extensive operations being performed under nitrous oxide, and on numberless occasions I have been asked thus to administer the gas for complete clearance of the teeth from both upper and the lower jaws and for other long dental operations. Picture what this means to the patient concerned. Consider the wounds made. I have measured many teeth and find that on the average the unerupted portion—that is to say, the portion from the gum margin to the apex, is 13 mm. If, therefore, ten teeth only, including one or two molars, are extracted, the sum of the depths of the sockets will amount to 150 mm., equalling a linear incision about *6 in. long.* But this is reckoning the depths of the sockets only; it does not take into account the superficial area of the whole of each socket, which cannot be less than, say, ¼ sq. in., making a total of approximately 2½ sq. in.

Imagine a skin wound 6 in. long, or more seriously 2½ in. square; imagine it left an open wound or covered with blood-clot, as in the case of the sockets, and assess what the "moral and intellectual damages" apart from the physical damage to the patient would be. Would the patient think of having such a wound made in the surgeon's consulting room and then go home afterwards? Would he not insist rather that the operation should be done in his own house or in a nursing home, so that, if he felt like it, he could immediately thereafter go to bed? Would he not expect every antiseptic precaution to be taken, proper dressings applied, all the ceremonial, all the solicitude of sympathetic friends usually associated with an Operation? Of course he would, and I hope that both surgeon and anæsthetist would be paid accordingly. But no one thinks anything of teeth, and the unfortunate anæsthetist, although he is the specialist who alone has made the operation possible and may have administered the anæsthetic with the greatest skill and with minimal interference with the patient's normal conditions and functions of life, receives but a small fee; because the patient does not realise either the experience or skill required, or the extent of his indebtedness; nor can he imagine what his sensations might otherwise have been. The dental surgeon is partly responsible for this; for some reason, I have not yet been able to discover, instead of putting all the facts before the patient and advising him that the operation is a major one and that it should be performed under ideal conditions, he makes light of the whole business and cannot therefore ask an adequate fee either for himself or for the anæsthetist. If patients were made to realise the truth and were made to understand what such an operation really involves, and if they were given the choice of having the operation done at one sitting in their own homes (or a nursing home) or of having it done piecemeal at the dentist's surgery, I believe they would plump for comfort every time and, moreover, would be willing to pay extra for it.

ABSORPTION OF TOXINS.

I have cited the instance of an ordinary superficial skin wound, but I cannot too strongly emphasise the fact that the wounds involved in the extraction of but ten teeth are far more serious. They are not merely superficial wounds in the gum but extend deeply into the cancellous tissue of the jaw bones. Such

tissue is notoriously very absorbent, and the patient may get a dangerous dose of toxin, because the tooth sockets immediately become filled with infected blood-clot, which is the best culture-medium in the world for pathogenic germs. For this reason many physicians advise, when patients are already debilitated by the absorption of toxins from chronic oral sepsis, or are suffering from some other disease in one or other of its protean forms which result from the absorption, that one or two teeth only be extracted at a time, and that when the patient has got over the direct effects of the extra dose of poison absorbed, the operation should be continued thus piecemeal until completion. They argue that if more than one or two teeth were taken out, the direct after-effects would increase in direct proportion and that the patient might be made more ill in consequence, because the tooth sockets would become heavily infected by the septic teeth remaining. I venture the opinion that this argument is fallacious, for my experience during the last 30 years is that patients suffer much less in every way if major dental operations are conducted in the manner I have suggested than they do when the operations are performed in successive stages. I believe that the sum of the results from the multiple successive doses of auto-intoxication is greater and more debilitating than are the results of the single dose of poison absorbed when the mouth is cleared of all septic material at one operation, because there are no teeth left to infect the sockets. I know of several cases that have suffered severely as the result of several successive extractions of acutely septic teeth with pyorrhœa. I know of one case of death, from pernicious anæmia, following this method of dealing with multiple dental caries; this patient was not suffering from pyorrhœa when the extractions began; he stated that his anæmia only began after the extractions were finished; he was not anæsthetised by me, but he told me that he was made increasingly ill by each successive administration of gas, and he attributed his anæmia to these repeated administrations. It is, of course, impossible to say if this were so, as no blood examinations were made until anæmia had manifested itself; but we do know that nitrous oxide gas does cause temporary blood changes, and it is not unreasonable to argue that if more gas is administered before the blood has had time to recover from the first dose, the more profound is the blood change likely to become and that possibly the organs concerned in blood-making may lose their recuperative power.

Recommendations.

So much for the old practice: what of the new? I submit for your consideration the following suggestions:—

1. That multiple extractions should be treated as one major operation.
2. That the patient should be medically examined before the operation is undertaken, having at the same time an examination of the blood.
3. That the patient should be properly prepared for the operation.
4. That the operation should be performed at the patient's own home or in a nursing home or hospital, so that immediately thereafter the patient can be put to bed and proper care and after-treatment be insured.
5. That a proper period of convalescence should be arranged for and that the patient should be immediately fitted with a temporary denture, so that he can partake of the diet he has found by experience best suited to him, and thus be saved from the risk of being half-starved, with its inherent danger of consecutive disease.

Some amplification of some of these points is necessary.

The *preparation of the patient* may include a course of heart tonics and correction of the low blood pressure usually associated with the condition necessitating these operations. A course of intestinal antiseptics may also be given and possibly ultra-violet irradiation both general and local. It must include suitable diet with a view to preventing subsequent acidosis, irrespective of whether chloroform is to be administered or not, because shock may be a factor in producing this serious sequela of operations.

The *place for operation* is, I consider, of extreme importance. If it is performed at home, not only is the patient saved unnecessary suffering, but we add materially to his comfort and shorten the period of his convalescence and ultimate restoration to health. Many risks inherent in the operation itself, and the risks of subsequent inflammation and general septic infection are obviated.

Convalescence is peculiarly the province of the physician, and its importance I think needs stressing somewhat, for in hospital practice, at least, patients are usually given no advice concerning it, but are allowed immediately to resume, if they can, their ordinary avocations. Generally they are unfit for this, and if they attempt it their convalescence is unduly protracted; they must be inefficient meanwhile, and during the period of debility they incur the risk of developing some general disease.

The importance of the temporary denture can be gauged by considering how much of a hard day's work can be efficiently performed on pap. I will not expatiate on the harmful effects of patients being left edentulous for several months; but I may mention that I have seen many adult patients who have suffered in mind, body and estate from not being able to eat anything but baby food, because they were left with no teeth.

Induction of Anæsthesia.

As I am not an operator, I can refer only to the medical and the anæsthetic aspect of operative technique. I submit that for the attainment of the best results the closest coöperation between doctor and dentist is necessary, before, during, and after the operation. In this connexion it goes without saying that a general anæsthesia must be maintained of sufficient duration for a possibly protracted operation. For this the patient should be properly prepared, since local anæsthesia or regional anæsthesia are inadmissible in these cases. I may here mention that on several occasions I have had to maintain general anæsthesia for over an hour for exceptionally difficult extractions; for instance, the removal of impacted and misplaced unerupted teeth necessitating sawing, drilling or chiselling away the surrounding bone; and more commonly, impacted lower wisdom teeth.

How, then, may such an anæsthesia be obtained? In my experience it is best to give a preliminary hypodermic injection of atropine gr. 1/100—and in certain cases this may be combined with gr. $\frac{1}{8}$ or gr. $\frac{1}{4}$ of morphia—half an hour before the operation. Morphia allays the patient's apprehension and is a great comfort to him; it is a comfort also to the anæsthetist because it inhibits reflex action and enables him to maintain a much lighter plane of anæsthesia than otherwise would be possible. In many cases this preliminary administration of morphia produces a prolonged anodyne effect and relieves the after-pain of the operation. The atropine diminishes the secretion of the salivary glands and of the mucous glands of the respiratory passages and so renders the field of operation more dry: thus the patient's respiration is not embarrassed by the mucus and salivary secretion even if ether be administered. Atropine also lessens the risk of post-operative bronchitis. If a full dose of atropine be administered, it is possible to give ether instead of chloroform throughout a very protracted operation. Atropine diminishes the reflex excitability of the vagus and thereby reduces the risk of reflex inhibition of the heart. Provided that a preliminary hypodermic injection of morphia and atropine can be given, it is possible to keep the patient anæsthetised with nitrous oxide and oxygen administered nasally for very considerable periods. Such an injection cannot, however, be given if the operation is to be performed at the operator's surgery or if the patient has to take a journey home immediately afterwards.

With more serious operations, such as removal of growths of the jaws or removal of the jaw itself, or even the removal of misplaced unerupted teeth and similar operations of a less grave nature, it is usually better to induce anæsthesia with a mixture of chloroform and ether and then continue with chloroform alone, administered by means of a Junker's apparatus through an oral or nasal tube. The posture of the patient is important. He should be recumbent on an operating table, with the left shoulder raised and the head turned slightly to the right, so that blood may drain into the lower cheek and out at an angle of the mouth, without the risk of becoming inhaled or swallowed, with the added danger of asphyxiation on the one hand, or of distressing after-vomiting on the other. With the patient in this position a sponge can be inserted into the mouth, serving the double purpose of absorbing blood and secretions and of acting as a screen, preventing any foreign body reaching the respiratory passages. If, however, the operator prefers to work with the patient in the sitting posture, this may be arranged, provided the anæsthetic is administered in this position from the outset. On very many occasions I have had to administer chloroform in the sitting posture because this posture is preferred by some operators; it certainly has the advantage of diminishing the bleeding, but undoubtedly it is more dangerous when the patient is under chloroform or ether.

Sequelæ of Operation.

The after-effects depend in direct ratio first and most importantly upon the duration of the anæsthesia; secondly, upon the amount of trauma caused in the mouth; and, finally, upon the amount of toxin absorbed.

The first two of these points need no amplification, for the moral they point is obvious—namely, that the patient should not be kept under the influence of the anæsthetic a moment longer than is absolutely necessary, and that the operation should be performed with the least possible damage to the tissues involved. The last depends partly upon the skill of the operator, partly upon the preliminary cleansing of the mouth, and chiefly upon the nature of the operation performed and the degree of cleanliness maintained after its completion. I have seen some operators—notably Mr. W. H. Dolamore, who I believe introduced the method—sew up the lacerated margins of the gums, after careful cleansing of the sockets, to prevent sloughing and to promote rapid healing. This method, in my experience, is followed by most satisfactory results. Others syringe out the cavities immediately after the extractions are complete and continue this antiseptic treatment throughout the convalescence. If these methods are employed, and if the after-care is properly conducted by the physician in charge, the patients suffer the minimal disturbance of the conditions and functions of life and the least possible shock and mental distress; their recoveries are amazingly rapid and the improvement in their general health after the removal of the source of their toxæmia is most gratifying to all concerned.

Mr. Geoffrey Keynes has prepared a "Bibliography of the Works of William Harvey," containing eight collotypes and numerous facsimiles in line. It will be published by the Cambridge University Press, in a limited edition of 300 copies, to celebrate the tercentenary of the publication of "De Motu Cordis."

Donations and Bequests.—Miss H. Knealy has given £3000 to endow a bed in the Royal Free Hospital for women authors and £4000 to endow a bed for journalists of either sex in a private ward to be named the "Knealy" Ward. These gifts are in memory of her brother.—The late Sir Harry Poland, K.C., among other bequests, left £500 to the Dover Hospital, Dover; £500 to the Mayor of Dover for the time being, for distribution amongst such charities in Dover as he, in his absolute discretion, may think fit; and £100 each to a number of medical charities.—Mr. Charles Coxhead, Lindsay, M.I.C.E., of Harley House, Regent's Park, N.W., besides other bequests, left £5000 to the Royal Hospital for Sick Children, Yorkhill, Glasgow, to endow a ward, £100 each to the Glasgow Royal Infirmary, the Western Infirmary, and the Victoria Infirmary, Glasgow.

AURICULAR FLUTTER.*

A STUDY OF FIVE CASES.

By HENRY MOORE, M.D., D.Sc. (N.U.I.),

PROFESSOR OF MEDICINE, UNIVERSITY COLLEGE, DUBLIN; VISITING PHYSICIAN, MATER MISERICORDIÆ HOSPITAL; AND CONSULTING PHYSICIAN, NATIONAL MATERNITY HOSPITAL, DUBLIN.

Auricular flutter is closely allied to fibrillation, but is much less frequently encountered. Lewis [1] has shown that auricular flutter is due to a "circus movement" in the auricles—namely, the continuous movement of a contraction wave in a ring of muscle, such as that which surrounds the mouths of the superior and inferior venæ cavæ or the mitral orifice. This revolving wave of contraction governs the movement of the auricles; it is inefficient as compared with the normal auricular systole; there is no starting-point, the wave moves continuously in a circular path, and its crest is separated from its wake by a gap of responsive and temporarily uncontracted muscle. Flutter may occur in paroxysms, appearing and disappearing abruptly, but once established it usually persists for months or years. The usual rate of the flutter circus movement is about 300 per minute. The ventricle can rarely respond to every auricular circus movement and it generally responds to each alternate one—2 : 1 block; the resulting ventricular tachycardia, however, is usually at a rate sufficiently high (generally about 150 per minute) to cause circulatory embarrassment.

In auricular fibrillation the rate of the auricular circus movement is higher, about 450 per minute, and the circus movement is irregular inasmuch as the same path is not followed from cycle to cycle; a single circus movement does exist, but the path changes constantly in its details while following the same general direction. In flutter the gap of responsive muscle between the crest and wake of the circus movement is about 1/5th of the whole circle in which the wave moves; in auricular fibrillation the gap is shorter and the wave of contraction flows through muscle in which more fibres are irresponsive. The close relation between flutter and fibrillation is shown by the fact that the former may pass into the latter under treatment. In flutter or auricular fibrillation, if the refractory period lengthens or the rate of propagation of the wave increases, the gap shortens; if the refractory period shortens or conduction decreases the gap widens. If the former changes are of such magnitude that the gap disappears the crest of the wave overtakes its wake; if, then, the muscle at the wake of the wave remains a little longer in the refractory state, the circus movement comes to an end. When this happens clinically the arrhythmia ceases and the dominant normal sinus rhythm is usually restored.

Action of Drugs on the Auricle.

(1) *Quinidine*,[2] by acting directly on the auricular muscle, prolongs the effective refractory period; it also shows conduction, and therefore the transmission intervals widen and the auricular rate diminishes. The lengthening of the effective refractory period tends to close the gap of a circus movement and to bring the latter to an end, whilst the slowing of conduction tends to have the opposite effect. It is only when the action of quinidine in lengthening the effective refractory period is greater than its action in slowing conduction that this drug is effective in abolishing clinical auricular fibrillation; thus is explained the fact that quinidine is therapeutically efficient only in about 54 per cent. of cases of auricular fibrillation. When it is unsuccessful its effect is probably more marked in slowing conduction (or the gap being shortened, owing to increase of the effective refractory period, the circus movement is diverted into a longer path, where a sufficiently large gap for its maintenance may persist).

---

* From the Mater Misericordiæ Hospital, Dublin.

Quinidine, also, partly (in experiments completely) depresses vagus action (probably by acting on the nerve ganglia), and it therefore acts indirectly on the auricular muscle by increasing the effective refractory period. These effects of quinidine are more in evidence in auricular fibrillation than in flutter. There is also evidence that this drug may produce delay in intraventricular conduction, which is evidenced electrocardiographically by changes in the height, width, and form of the Q R S complex (as illustrated in Case 2).

(2) *Digitalis.*[3]—Full therapeutic doses of this drug, by increasing vagal tone, reduces the length of the refractory period and tend to increase the rate of conduction; digitalis, therefore, usually increases the rate of the circus movement in auricular fibrillation. On the other hand, by acting directly on the heart muscle, it increases the length of the refractory period, and, when the heart muscle is responding rapidly, retards conduction and therefore tends to decrease the rate of the auricular oscillations. The predominant action of the drug seems to be through the vagus, because in practice the rate of the auricular oscillations in fibrillation are, as a rule, somewhat increased. From the point of view of closure of the gap, however, these two actions are opposed to each other, and therefore the circus movement is rarely abolished by digitalis action. Lewis showed that flutter may frequently be converted into fibrillation by the action of digitalis, and that, if the drug be then discontinued, normal sinus rhythm will often appear. It is not fully understood how flutter may be converted into fibrillation by the use of digitalis; the fundamental differences between the two conditions seem to be that in fibrillation the refractory period is less, the path of the circus movement shorter, the rate of the circus movement greater, and the gap smaller than in flutter; if, now, the vagus action of digitalis is predominant in flutter the refractory period is shortened, conduction rate is increased, and the rate of the circus movement is increased; the gap may therefore become shorter. In other words, there is a shifting of all these properties in a direction which could, one would suppose, favour the conversion of flutter to fibrillation.

The treatment of auricular fibrillation with digitalis and quinidine is fairly well understood and comparatively successful, but, since flutter is relatively rare, reports of its treatment are not numerous. There seems to be a common belief that quinidine should not follow digitalis without an interval, but it is not easy to discern any reason why one should wait until the digitalis effect has worn off—indeed, the argument seems to point the other way.

This paper records five cases of auricular flutter which may be of interest.

CASE 1.—It was not possible to study this case in detail. Clergyman, aged 69 years, seen July 9th, 1923. Height 6 ft. 2 in. Family history and previous history not relevant.

Complaint.—Palpitation and rapid pulse-rate for two years previously; some breathlessness on moderate exertion; feet and ankles became swollen towards evening; the patient, however, stated that he was not greatly restricted in his activities and could attend to his duties fairly efficiently.

Physical Examination.—Radial and brachial artery walls slightly thickened; retinal arteries appeared normal; heart found on palpation and percussion to be slightly enlarged to the left. Pulse-rate varied from 108 to 120 and the pauses between the beats were often somewhat unequal, but there was no gross irregularity; the beats were of equal strength. Blood pressure 180/80. The urine contained a trace of albumin and occasional granular casts, calcium oxalate crystals, and a few white and red blood cells. The prostate was somewhat enlarged. There were no other abnormalities on clinical examination. An electrocardiogram† showed auricular flutter with 2 : 1 to 3 : 1 block (Fig. 1). Pressure over the vagi did not slow the pulse.

Treatment.—The patient received 1 g. of digipuratum and grs. 13½ of powdered digitalis leaves over four days; on the third day the pulse-rate began to drop and on the fourth it was about 70 per minute. An electrocardiogram then showed that auricular flutter still persisted, but that the degree of block had increased to 4 : 1, giving a pulse-rate of about 70; the blood pressure was 186/100. 30 minims of tincture of digitalis per day, by mouth, sufficed to keep the ventricular rate thereafter about 70 per minute. The patient was advised to take the 30-minim dose of tincture of digitalis every day and was given suitable instructions in relation to work, diet, and exercise; he was discharged on the understanding that he was to report from time to time. He was not seen again until July 24th, 1924, when I was called to the country to examine him. He was suffering from mental confusion with some cerebral excitement; the axillary temperature was 100° F., but physical examination was otherwise negative; he was still taking the digitalis as prescribed, and his pulse was regular at a rate of 76 per minute. The blood pressure was 200/110. It was not possible to get a polygraph tracing. He was put on a salt-poor diet and made a complete recovery in a few weeks. He paid a flying visit in May, 1925, and appeared to be in good health with pulse-rate 76 and regular, blood pressure 176/100, and heart only slightly enlarged to the left. He was still taking digitalis. He was advised to come for electrocardiographic examination, but did not do so until Sept. 5th, 1925; at that time the pulse-rate was regular at 74 per minute, blood pressure 172/102, and the heart slightly enlarged to the left; he looked and felt well and was able to carry on his work at a slightly reduced level in comfort. The electrocardiogram showed sinus rhythm, flutter having disappeared, with splintering of Q R S in lead III. (place accidentally destroyed). He was advised to discontinue the digitalis, which he was still taking. He reported on Jan. 10th, 1926, and was found to be in good health and fairly active; the pulse-rate was 74 and regular. He refused electrocardiographic examination. He returned again on May 30th, 1927; he stated that he was comparatively well and was able to walk, at a moderate rate, from four to six miles per day and to carry out his duties fairly efficiently. For the last three weeks he had noticed that his pulse was slightly irregular, but this did not cause him any inconvenience. His blood pressure was 170/110 and pulse-rate 102. The impulse beat was 12·5 cm. from the middle line in the fifth space. The radial artery walls were normal or very slightly thickened. The pulse was slightly irregular in rate and perhaps in force. Electrocardiographic examination showed auricular flutter with 4 : 1 block, otherwise the electrocardiogram was normal. He had not used salt for almost three years. In view of the fact that the circulation seemed to be fairly efficient, that there was a 4 : 1 block, and also because of his age and of the possibility of intra-auricular thrombi, it was decided not to attempt to abolish the flutter. He was accordingly advised to take 22 minims of tincture of digitalis once a day. He was seen again on August 20th, 1927; at that time the blood pressure was 156/92, the impulse beat was 13·5 cm. from the middle line, and the pulse-rate was 74 and regular; he had given up taking digitalis for two weeks previously. The electrocardiogram revealed auricular flutter with a 4 : 1 ventricular response (Fig. 2). He stated that he felt well and could attend to his work and take a moderate amount of exercise without inconvenience. He returned again on Oct. 4th, 1927, complaining of slight breathlessness on exertion. The electrocardiogram now showed flutter with 2 : 1 to 3 : 1 block and the pulse-rate was about 108 and slightly irregular; he had taken no digitalis for about eight weeks. The blood pressure (auscultatory method) was 170/90; it was noticed that only half the beats came through to the wrist, or were audible over the brachial artery, from 170 to 120 mm. Hg during decompression of the armlet of the sphygmomanometer, but all came through from 120 to 90 mm. Because these features seemed to indicate a doubtful prognosis, and because of apparent escape of the auro-ventricular node from digitalis control, with consequent increased ventricular rate, the patient was again put on digitalis—27 minims of the tincture per day. When seen on Oct. 27th, 1927, he was still taking digitalis as prescribed, the pulse-rate was 86 per minute, and his only complaint was very slight breathlessness on moderate exertion and consciousness of his heart beat when lying on his left side; he stated that he felt improved; the electrocardiogram showed flutter with 3 : 1 to 5 : 1 block (occasionally 2 : 1); the pulse-rate was 90 and slightly irregular; the blood pressure was 152/90, all beats coming through to the wrist at 152 mm. Hg. The patient returned on Dec. 5th, 1927; he was still taking 27 minims of tincture of digitalis per day; the blood pressure was 172/84, pulse-rate 76 and regular, and impulse beat about 11 cm. from the middle line. The electrocardiogram showed sinus rhythm (Fig. 3); a few days after his previous examination (Oct. 27th, 1927) he became aware that the slight breathlessness on exertion had disappeared and that he was no longer aware of the beating of his heart when lying on his left side as he had been for some months previously. When, in what manner, and why flutter disappeared cannot be stated, but apparently our fear in this case that the inducting of sinus rhythm might cause detachment of thrombi was groundless.

† Time marker shows fifths and twenty-fifths of a second; 1 cm. excursion of string is equal to one millivolt. The tracings are reduced for publication.

Comment on Case 1.

It is unprofitable in this case to speculate on when or how, in the first instance, auricular flutter gave place to sinus rhythm, as the observations were of necessity so infrequent and imperfect. It is interesting to note the relapse to flutter which apparently occurred after an interval of almost two years, as far as one can judge from the history. Final treatment directed towards the abolition of flutter and the restoration of sinus rhythm (by larger doses of digitalis followed by quinidine as described later) was considered unwise in this patient owing to the possibility of the presence of intra-auricular thrombi, which might become detached if sinus rhythm were induced, the age and the likelihood of progressive degenerative myocardial change; moreover, the efficiency of the circulation was quite good when digitalis was given in such daily doses that 3 : 1 to 4 : 1 auriculo-ventricular block was maintained even while auricular flutter continued. However, sinus rhythm appeared finally after some months of digitalis treatment without quinidine and with no untoward results. It is of interest to note the presence of flutter at a comparatively advanced age—flutter was last observed when the patient was 73 years old—especially as the consequent heart failure was easily controlled by digitalis and as flutter finally disappeared with no symptoms of detachment of intra-auricular thrombi.

CASE 2.—A farmer, aged 39 years, consulted me on Dec. 15th, 1925. He was 6 ft. 1½ in. in height and weighed 240 lb. He complained of fluttering in his chest and dyspnœa on slight exertion.

Previous History.—Measles and mumps in childhood; typhoid fever when 18 years old; gonorrhœa 12 years ago. Both knees became swollen and painful nine years ago and there was also slight swelling of the ankles; he recovered after about ten days in bed and does not know whether he had a rise of temperature; his tonsils were removed ten months later, although he was never subject to sore-throat.

Present Illness.—On Dec. 1st, 1925, he noticed dyspnœa, palpitation, and tachycardia on slight exertion, but these symptoms disappeared on resting; since then the same symptoms had recurred several times, sometimes while resting, but they were especially prone to appear after breakfast or on exertion. I saw him for the first time in an attack which had apparently persisted for at least six days.

Physical Examination.—Face slight cyanotic, slight œdema of legs, heart seemed somewhat enlarged to the left, but difficult to map out. No cardiac murmurs. Pulse and heart-rate about 172 per minute and regular. Liver and spleen not palpable. Lungs normal. Blood pressure 112/90. Blood Wassermann reaction negative. The electrocardiogram showed auricular flutter, with 2 : 1 block (Fig. 4). Pressure over vagi or eyeballs did not slow the pulse.

Course and Treatment.—It was decided to try the effect of quinidine sulphate by mouth after the administration of 0·4 g. had shown that the patient did not have an idiosyncrasy for the drug. From Dec. 18th to 24th 14·8 g. of quinidine sulphate were given by mouth, in doses of 0·4 g. as follows:—

Dec. 18th ..	1 × 0·4 = 0·4 g.	Dec. 22nd ..	6 × 0·4 = 2·4 g.
,, 19th ..	4 × 0·4 = 1·6 g.	,, 23rd ..	5 × 0·4 = 2·0 g.
,, 20th ..	5 × 0·4 = 2·0 g.	,, 24th ..	3 × 0·4 = 1·2 g.
,, 21st ..	13 × 0·4 = 5·2 g.		

After 9·2 g. of the drug had been taken (Dec. 21st) the flutter waves became increased in length, apparently due to slower auricular conduction, and their rate was slower than on admission. After 11·6 g. of quinidine (Dec. 22nd) these changes in the flutter waves were still more marked, and the Q R S complex, in addition to showing a varying voltage, manifested aberration in many beats (interference with the spread of the excitation wave through the ventricle); moreover, there seemed to be a tendency on the part of the ventricle to respond more frequently to the individual flutter waves (Fig. 5). Evidently these electrocardiographic changes were evidences of the toxic action of quinidine on the conduction-genetic system. The patient, whose clinical condition was quite unchanged and who was fairly comfortable while resting, then decided, against advice, to go home for Christmas.

He was readmitted on Jan. 6th, 1926. His clinical condition was about the same as on the first admission, and the electrocardiogram again showed auricular flutter, with 2 : 1 block. It was now decided to try the effect of digitalis. The preparation used was digipuratum (Knoll), given by mouth in tablet form. Previous experience had shown that full clinical digitalisation in auricular fibrillation is nearly always obtained with digipuratum by the administration by mouth of 1 g. to a patient of average weight. 1·1 g. had been given by mouth in divided doses over three days when the arrhythmia suddenly changed from auricular flutter to auricular fibrillation, the pulse- and heart-rate dropping to about 82 per minute and being fairly regular (Fig. 6). The patient now found that he could undertake moderate exercise with comfort. He again insisted on leaving the hospital to transact some urgent business (Jan. 10th), not taking digitalis.

He returned on Jan. 20th, 1926, in the same condition as on the first occasion, and the electrocardiogram showed auricular flutter with 2 : 1 block. From Jan. 21st to 22nd he received 1 g. of digipuratum in divided doses, and shortly after the last dose auricular fibrillation appeared again. As he again wished to leave hospital we decided to endeavour to induce the return of the normal rhythm with quinidine; consequently, after waiting in vain for 24 hours in the hope that, on the cessation of the digipuratum treatment the normal rhythm would appear, 2·4 g. of quinidine sulphate were given in doses of 0·4 g. every second hour. An electrocardiogram taken one hour after the last dose showed normal sinus rhythm (Fig. 7). The patient now felt quite comfortable, even on considerable exertion, and left hospital on Jan. 26th with normal cardiac rhythm, pulse- and heart-rate about 80, and blood pressure 124/76. He returned on Feb. 13th and April 21st for examination and electrocardiogram, and was in every respect normal.

On August 10th, 1926, the patient was once more admitted, suffering from an attack of auricular flutter, with 2 : 1 to 4 : 1 block, which had commenced ten days previously, the signs and symptoms being practically the same as on the first occasion. Eight-tenths of a gramme of digipuratum caused no change in the electrocardiogram; after 24 hours' interval quinidine was started and 4·8 g. were given over a period of two days, when the electrocardiogram again showed lengthening and diminished voltage of the flutter waves (2 : 1 block) with occasional slight aberration. The quinidine was then stopped. In 24 hours the flutter waves were of the same type as on admission with 2 : 1 to 4 : 1 block. After two days' interval (flutter still present) it was decided to push digitalis in the hope of again inducing auricular fibrillation, and 2·1 g. of digipuratum were given in divided doses over four days. One hour after the last dose of the 2·1 g. of digipuratum the pulse-rate suddenly fell to about 70 per minute and the electrocardiogram showed auricular fibrillation. No drug was given now for 48 hours, in the hope that on the withdrawal of digitalis auricular fibrillation would give place to normal rhythm; as fibrillation persisted 2·4 g. of quinidine sulphate were given in divided doses of 0·4 g. every two hours, and about one and a half hours after the last dose an electrocardiogram showed normal sinus rhythm with a pulse-rate and heart-rate of 76. The patient was discharged in a few days with a normal rhythm, feeling quite well even after moderate exercise.

On May 26th, 1927, he returned once more, complaining that his heart trouble had suddenly developed on May 25th at about 9 P.M. Between the onset of the attack and his visit he had taken 1 g. of digipuratum by mouth. The pulse-rate was 140 per minute and slightly irregular. The electrocardiogram showed auricular flutter with 2 : 1 to 3 : 1 heart-block. He received 3·6 g. of digipuratum by mouth between the onset of this attack of flutter on May 25th and the appearance of auricular fibrillation on May 30th. It is to be noted that in this attack a large dose of digitalis was necessary to induce auricular fibrillation. On June 1st (fibrillation still present) he was given 0·4 g. of quinidine at 6 A.M., 8 P.M., and 10 A.M. (total 1·2 g.); about 11 o'clock on that morning he noticed a slight palpitation, and then he said that he felt his pulse had become steady and that he was no longer conscious of abnormal beating of the heart. He was electrocardiographed at 12 noon on the same day; the tracing showed normal sinus rhythm with a pulse-rate of 84. He was discharged that afternoon, as he had urgent business, on small doses of digitalis (12 minims of the tincture once daily). During this period in hospital a careful search was made for septic foci, and the only positive finding was by roentgenographic examination of the teeth, carried out by Dr. J. A. Geraghty, which revealed an abscess around the posterior root of the first right upper molar tooth; the tooth was extracted. On Oct. 1st, 1927, he reported that he was still well. He discontinued the digitalis in the first week of October, 1927. He returned to hospital on Nov. 17th with a pulse-rate of 140 and auricular flutter (2 : 1 block); flutter had apparently reappeared on Nov. 7th. On Nov. 18th, at 2.30 P.M., he had received 1·2 g. of digipuratum in divided doses, and the electrocardiogram at that time showed flutter 3 : 1 to 8 : 1 block; at 3 P.M. he got 0·4 g. digipuratum (total 1·6 g.), and at 6.15 P.M. on the same day auricular fibrillation was present. Next day, at 7.30 A.M., auricular fibrillation was still shown in the electrocardiogram, and 1·2 g. of quinidine was subsequently given in divided doses; at 11.30 A.M. the patient noticed some vague changes in his heart beat; at 11.42 P.M. the electrocardiogram showed sinus

ELECTROCARDIOGRAMS RECORDING RESULTS IN TREATMENT OF AURICULAR FLUTTER.

rhythm, and the pulse-rate was 82 and the blood pressure 118/80; he was discharged feeling quite normal and directed to take 22 minims of tincture of digitalis per day. He has remained well up to the present time.

Comment on Case 2.

This case apparently illustrates the toxic effects of moderate doses of quinidine on the myocardium in auricular flutter as evidenced by the electrocardiograms—viz.: (*a*) delayed interauricular conduction and slowing of the rate of the auricular (flutter) circus movement; (*b*) ventricular aberration. These changes were taken as showing that further quinidine dosage might not be safe, and the drug was discontinued. Quinidine alone proved ineffective in abolishing auricular flutter. Digitalis alone in adequate dosage caused flutter to be replaced by auricular fibrillation, but flutter reappeared later on cessation of digitalis treatment. When auricular fibrillation replaced flutter as an effect of digitalis, a small amount of quinidine was sufficient to cause a return of normal sinus rhythm in a few hours without any "toxic" signs appearing in the cardiogram. Flutter reappeared after an interval of something over seven months and normal rhythm was restored by digitalis followed by quinidine, as on the first occasion (when quinidine alone, not preceded by digitalis, failed). Once again, after a further interval of almost ten months, flutter occurred, and on this occasion a large dose of digitalis was required to transform the arrhythmia to fibrillation, but when this was accomplished a small dose of quinidine was sufficient to restore sinus rhythm. An alveolar root abscess was the only septic focus discovered. Finally, after something over seven months, the patient discontinued the digitalis, and flutter recurred after about five weeks; on this occasion digitalis caused flutter to be replaced by fibrillation in 28 hours, and subsequently small doses of quinidine succeeded in replacing the latter by normal sinus rhythm. Thus four attacks of flutter occurred in two years, and each attack yielded to digitalis followed by quinidine, with restoration of sinus rhythm.

CASE 3.—Housewife, aged 50 years, was seen on Dec. 13th, 1926, complaining of palpitation and breathlessness on exertion. Family history not relevant.

Previous History.—Measles and scarlet fever in childhood; "inflammation" of her "throat" 20 years ago; since then frequent "sore-throats"; peritonsillar abscess opened three years ago; frequent attacks of acute rhinitis and bronchitis; varicose veins in legs; all teeth extracted four years ago. Two children born dead at full term; no living children. Venereal disease denied.

Complaint.—Dyspnœa and palpitation on slight exertion.

Present Illness.—A year ago when running she had an attack of "palpitation" accompanied by dyspnœa. Since then she experienced several similar attacks on exertion. In October, 1926, she had acute bronchitis accompanied by palpitation and dyspnœa. She apparently recovered from the bronchitis, but the palpitation became progressively worse on exertion and recently appeared on even slight physical effort.

Physical Examination.—Pulse 166 and respirations 26 per minute. Temperature (mouth) 98·8° F. The pulse was regular with occasional dropped beats, and all cardiac systoles gave rise to a pulse at the wrist. The face, hands, and feet were cyanosed, and there was moderate dyspnœa at rest. The tonsils were hypertrophic and the submaxillary lymph-glands and the superficial cervical glands along the right sterno-mastoid were enlarged. Sibilant rhonchi were heard diffusely over the lungs and crepitations at the bases; there was impaired resonance and feeble breath sounds over both bases. The heart was enlarged to the left, the impulse being in the fifth intercostal space, 11·5 cm. from the middle line; a mitral systolic murmur was heard over the apex and transmitted to the left axilla; there was slight accentuation of the aortic second sound. There was slight œdema of the shins and ankles. The abdominal reflexes were absent. The blood pressure was 190/140. The right lobe of the thyroid gland was slightly enlarged and firm and could be palpated by Lahey's "dislocation" method; there was a fine tremor of the hands (rate about 4 to 6 per second). The urine contained no albumin, sugar, or casts. The patient was freely coughing up a moderate amount of mucoid sputum. There were no other abnormalities on clinical examination. Blood chemistry: Urea nitrogen, 11·6 mg.; non-protein nitrogen 20 mg., uric acid 3 mg., and creatinin 1·4 mg. per

100 c.cm. of blood. Urea-concentration test normal (2·3 per cent.). Fixation of specific gravity and water excretion tests indicated slight kidney deficiency. A provisional diagnosis was made of auricular flutter, myocardial failure, mitral incompetence, chronic bronchitis, and congestion of the bases of the lungs. The blood Wassermann reaction was ++. An electrocardiogram showed auricular flutter with 2 : 1 to 3 : 1 block (Fig. 8). The patient had been getting 5 minims of tincture of digitalis for ten days previously. After the tachycardia has been successfully treated the basal metabolic rate was found to be +32 per cent.; there were no hyperthyroid eye signs, and it was concluded that the right thyroid lobe probably contained a "toxic adenoma." Pressure over the vagi or eyeballs did not slow the pulse.

Treatment.—Between 12 midnight, Dec. 13th, and 1.30 A.M., Dec. 14th, 1·6 g. of digipuratum was given in divided doses. The pulse-rate remained at about 160 until 1.30 A.M. on Dec. 14th, when it suddenly fell to about 68 and was slightly irregular. An electrocardiogram taken on Dec. 14th at 11.30 A.M. showed auricular fibrillation (Fig. 9), the pulse-rate at this time being around 90 per minute. Several electrocardiograms were thereafter taken on Dec. 15th and 16th, and showed, generally, an increasing ventricular rate and auricular fibrillation. It was decided to endeavour to abolish the fibrillation and induce the return of sinus rhythm by the administration of quinidine. Accordingly 0·2 g. of quinidine sulphate was given orally at 12.10 P.M. on Dec. 16th; as there were no signs of idiosyncrasy, 0·4 g. was given at 3 P.M., 0·4 g. at 4 P.M., and 0·4 g. at 5.30 P.M. on the same day. At 6.5 P.M. an electrocardiogram showed that sinus rhythm had appeared with occasional ventricular extrasystoles (Fig. 10). Six hours later the extrasystoles became more frequent (about 1 in 5). A few hours after the appearance of auricular fibrillation and the slowing of the ventricular rate, the cyanosis and dyspnœa disappeared, and a little later the œdema vanished and the congestion of the pulmonary bases showed signs of clearing up; two days later the latter had completely disappeared, and on Dec. 19th the patient was able to walk about the ward without discomfort (she was kept in bed during the active treatment). She was discharged a few days later feeling quite well. Antisyphilitic and, indeed, any form of treatment was refused.

Up to June 1st, 1927, there was no return of flutter, but extrasystoles were present, varying from 1 in 3 to 1 in 10 (Fig. 11); the patient felt well and was able to take moderate exercise without discomfort. On June 17th, 1927, she returned complaining of dyspnœa and palpitation; there was cyanosis, slight œdema of the feet, and copious mucopurulent sputum; sonorous and sibilant rhonchi were heard over the lower lobes of both lungs, the resonance of which was diminished on percussion; temperature 97° F. (axilla), respirations 26, and pulse-rate 150 and regular; a mitral systolic high-pitched blowing murmur was heard and transmitted to the axilla; the cardiac impulse was located in the fifth intercostal space 13 cm. from the middle line. The patient was noticeably drowsy and apathetic. The blood pressure was 102/78. The electrocardiogram showed auricular flutter with 2 : 1 block. From 9.20 P.M., June 17th, to 12.30 P.M., June 19th, the patient received 2·1 g. digipuratum by mouth in divided doses, but, owing to occasional vomiting, which began 20 minutes after the first dose and continued irregularly throughout the administration of the digipuratum, it is impossible to know how much of the drug was absorbed. During this period the pulse-rate gradually slowed down; at 12.30 P.M., June 19th, it was fairly steady at 70 per minute and the electrocardiogram showed flutter with 3 : 1 to 4 : 1 block. On June 20th, after the patient had received the relatively large dose of 2·9 g. of digipuratum, auricular fibrillation appeared. An interesting additional arrhythmia now, however, appeared for the first time in addition to fibrillation; the patient exhibited attacks of tachycardia of 15 to 45 seconds' duration, the pulse-rate suddenly changing from about 86 to 150 per minute. It was difficult to get good tracings of the tachycardia owing to restlessness, but Fig. 12 illustrates the findings. Evidently this new arrhythmia was an example of the comparatively rare condition known as ventricular tachycardia. It is interpreted as such because (*a*) the auricles were fibrillating, and therefore it could not have an auricular origin; (*b*) because the ventricular complexes were distinctly abnormal in form; and (*c*) because of the presence of somewhat similar ectopic beats before (Fig. 11) and after (Fig. 13) the paroxysms.[4] It is probable that the attacks of tachycardia, which apparently arose from a focus in the left ventricle, were due to digitalis intoxication, because they became shorter and more infrequent from the cessation of digitalis therapy on June 20th and were no longer present on June 24th, when only occasional extrasystoles of similar form were seen. Fibrillation, however, persisted. It was now judged safe to give quinidine sulphate by mouth, and on June 24th 1·6 g. was given in divided doses. Two and three-quarters hours after the last dose of quinidine sinus rhythm was shown in the electrocardiogram with ventricular extrasystoles (Fig. 13). The pulse-rate next day was now about 80 and regular, the impulse 12 cm. from the middle line (fifth space), the mitral systolic murmur was still heard, and in addition to this a faint mitral murmur was heard in late diastole. The drowsiness, cyanosis, and dyspnœa had completely passed off and the patient was quite comfortable. She was discharged a few days afterwards on antisyphilitic treatment and taking 22 minims of tincture of digitalis per day. On Sept. 14th, 1927, sinus rhythm was still present with occasional extrasystoles arising, sometimes in the left and sometimes in the right ventricle; the P wave was normal in type and the pulse-rate was 88 per minute. The basal metabolic rate was +28 per cent., the diastolic murmur had disappeared, and the patient stated that she felt well. She was still taking digitalis, as prescribed above, on Dec. 6th, 1927, and flutter had not recurred.

This patient was placed under restraint on Dec. 18th, 1927, suffering from melancholia. She died in January, 1928, in mania, but her heart was reported as consistently normal by the physician in whose charge she was. An autopsy was not obtained.

Comment on Case 3.

Auricular flutter gave place to auricular fibrillation after digitalisation, and fibrillation, in its turn, was abolished by quinidine, sinus rhythm being restored. The case relapsed to flutter after six months and once again the same form of treatment was successful; on this occasion, however, paroxysmal ventricular tachycardia appeared as a toxic digitalis effect at a time when auricular fibrillation was present, and quinidine treatment, which was delayed four days until the ventricular tachycardia disappeared, was again successful in restoring sinus rhythm.

CASE 4.—Housewife aged 46. Admitted Jan. 19th, 1927, from county home in such a serious condition that no history was obtained. Heart-rate 216 per minute and regular, no murmurs heard; pulse could not be felt at the wrist; respirations 34 and temperature 96·2° F. (axilla). Cyanosis of hands, feet, and face; orthopnœa and dyspnœa. Blood pressure could not be read by auscultatory method. Impulse beat in anterior axillary line, liver edge felt 3 cm. below costal margin; loud rhonchi heard over thorax and moist crepitations heard at pulmonary bases. No œdema of legs. Electrocardiogram (Fig. 14) showed auricular flutter with 1 : 1 response—the ventricle responding to each circus movement in the auricle. Pressure over vagi or on eyeballs did not slow the pulse. A hundredth of a grain of strophanthin was given intravenously, after which the pulse temporarily returned to the wrist, but death occurred in two hours.

Permission for a complete autopsy was refused, so the heart alone was examined by Dr. A. R. J. Dungan. The right ventricle was markedly dilated, the myocardium being very much thinned out at the apex; posterior cusp of mitral valve was a little shortened and thickened, and aortic cusp of mitral valve had a thin ridge of minute organising vegetation along its line of closure; the root of the aorta had small patches of commencing atheroma and the coronary arteries showed similar changes, but so slight as to produce no narrowing. Sections showed some fatty degeneration of the muscle-fibres of the right auricle in the neighbourhood of the upper third of the sulcus terminalis, and a certain amount of hæmorrhage in its lower third.

In the vast majority of cases of auricular flutter there is some degree of A-V block, and only rarely do the ventricles respond to each auricular circus movement as in this patient. Only about 18 cases of flutter with 1 : 1 ventricular response are recorded.

CASE 5.—A business man, aged 60, was admitted on March 5th, 1928. Height, 5 ft. 11 in.; weight, 190 lb.

Complaint.—Breathless on exertion and slight swelling of the lower legs towards evening.

Previous History.—Smokes about 40 cigarettes a day; otherwise irrelevant.

Physical Examination.—Pulse-rate, 144; impulse beat, 9·5 cm. from middle line in fifth space. Only three teeth of his own and these show pyorrhœa and one is crowned. Moderate œdema of lower legs. Crepitations at both pulmonary bases. Blood pressure 112/92. The electrocardiogram shows auricular flutter with 2 : 1 block.

Treatment.—1·6 g. of digipuratum caused flutter to give place to auricular fibrillation in 28 hours; the digitalis was then stopped and normal sinus rhythm appeared four hours afterwards. The pulse-rate was then 56 per minute, the blood pressure 130/78, and the crepitations at the pulmonary bases and the œdema of the legs had disappeared. He was discharged on a daily dose of 20 minims of tincture of digitalis.

Twenty-two days later flutter had not recurred, the blood pressure is 142/76, the pulse-rate 72 per minute, and he feels and looks in good health in every respect. He has reduced his cigarettes to 16 per day and has promised to get the three teeth extracted.

Summary.

Five cases of auricular flutter are described. In the first case sinus rhythm appeared after an unknown interval following digitalis treatment, but relapse to flutter occurred later; adequate digitalis administration, however, caused the maintenance of 4 : 1 block between the fluttering auricles and the ventricles with the result that the circulation was quite efficiently carried on. In certain cases of flutter established for a considerable length of time, especially if associated with congestive heart failure, the possibility of the presence of auricular thrombi and of their detachment after the appearance of sinus rhythm should be considered. This consideration led us to believe that a combination of digitalis and quinidine treatment in this case might be inadvisable, especially as digitalis alone produced a degree of block which permitted of a sufficiently low ventricular rate. Eventually, however, and without quinidine, sinus rhythm reappeared while the patient was taking digitalis with no untoward results.

In the second and third cases digitalis in suitable dosage on each occasion caused flutter to be replaced by auricular fibrillation, which, in its turn, gave place to sinus rhythm as a result of treatment with quinidine. In the second case, although auricular fibrillation appeared after digitalis treatment, relapse to flutter occurred on discontinuance of the digitalis when quinidine was not used after fibrillation appeared, whilst quinidine alone in moderately large doses was unsuccessful in the treatment of flutter, but caused changes in the electrocardiograms which might be interpreted as evidence of toxic action. Each of the three relapses in the second case from sinus rhythm to flutter, as well as the first attack of flutter, was controlled by digitalis followed by quinidine; digitalis caused flutter to be replaced by fibrillation, and quinidine caused the latter to be replaced by sinus rhythm. A large dose of digitalis, however, was required on the second occasion to convert flutter to fibrillation. The two attacks of flutter in the third case were also successfully treated by digitalis followed by quinidine, but the large dose of digitalis given in the relapse caused transitory paroxysmal ventricular tachycardia.

Cases 1, 2, and 3 illustrate the tendency for auricular flutter to reappear after successful treatment.

The fourth case was an example of a comparatively rare condition; auricular flutter with 1 : 1 ventricular response.

In the fifth case flutter gave place to auricular fibrillation after digitalis and fibrillation was spontaneously replaced by sinus rhythm four hours afterwards.

Many cases of auricular flutter may be successfully treated by full digitalisation [5] with the object of inducing the appearance of auricular fibrillation; if then digitalis be stopped, normal sinus rhythm may replace fibrillation, as has been shown by Lewis. If sinus rhythm cannot be restored in this manner, fibrillation still persisting, it is suggested that the latter condition may be treated with quinidine with the object of restoring sinus rhythm. This procedure—digitalis followed by quinidine—was successful six times in two of the cases of flutter reported in this study.

THE POSITION OF HISTOLOGY IN THE PROGNOSIS OF CARCINOMA OF THE BREAST.

BY D. H. PATEY, M.S. LOND., F.R.C.S. ENG.,
SURGICAL REGISTRAR, MIDDLESEX HOSPITAL;
AND
R. W. SCARFF, M.R.C.S. ENG.,
ASSISTANT PATHOLOGIST, BLAND-SUTTON INSTITUTE OF PATHOLOGY, MIDDLESEX HOSPITAL.

CASES of carcinoma of the breast are usually classified microscopically according to two standards; one method is by the arrangement of the cells, which may be in masses, in solid columns, or in tubules; the other is by the relative amounts of epithelial elements and fibrous tissue. Depending on the former grouping spheroidal-celled carcinomata and adenocarcinomata are described, whilst, with the latter standard, the designations "atrophic scirrhus," "scirrhus," and "medullary" or "encephaloid" are employed. Speaking generally, the prognostic value of these terms has been disappointing. Attempts have recently been made to put the subject on a more satisfactory basis. Greenough,[1] in America, and Delbet,[2] in France, have made extensive studies and published their conclusions. The former has applied the theory of dedifferentiation, used by Broders [3] in other regions, to carcinoma of the breast, and has analysed under nine headings the histological factors which may be of importance. He states, however, that "the pathological classification of these specimens rests upon the estimate of the individual observer and the weight he is inclined to give to a number of different factors." Delbet, on the other hand, rejects the theory of dedifferentiation, but recognises different morphological and physiological types of growth of varying degress of malignancy.

The histological picture, however, has been studied without due regard to the other features of the case which influence the prognosis. For example, however relatively innocent a tumour may appear under the microscope, the prognosis must be hopeless if, at the time of the operation, the disease has passed outside the field of surgical interference. On the contrary, the relative malignancy of a growth which has been completely removed when in the early or local stage is a matter of theoretical importance only. If, therefore, the histological appearance of the growth is to be of any value in giving a prognosis in an individual case, account must also be taken of the stage which the disease has reached when the patient presents herself for treatment. The best index of the degree of spread is afforded by examination of the axillary glands, the importance of which was first pointed out by Halsted and has more recently been elaborated in the Leeds figures of the Ministry of Health.[4]

Signs of Prognostic Value.

The present study was undertaken in an attempt to ascertain if there is any correlation between the histological appearance of the growth and the subsequent course of the disease, and to determine the value of such an analysis in giving a prognosis in an individual case when all the ascertainable factors have been taken into account.

Greenough's method of classification has been largely followed, but chief importance has been attached to three factors—tubule formation, inequality in size of nuclei, and hyperchromatism.

Tubule formation has been considered of favourable significance. Marked inequality in size and irregularity of outline of the nuclei has been taken to be indicative of a high degree of malignancy, and the presence of many hyperchromatic nuclei has also been considered to affect the prognosis adversely.

The amount of secretion and number of mitotic figures have been taken as qualifying the above, the former favourably and the latter unfavourably. Other

points, such as degeneration of cells, small round-celled infiltration, and hyalinisation of stroma have been noted, but little weight has been attached to them. Irregularity in size of cells has been considered together with irregularity in size of nuclei, but the estimation is often difficult owing to indistinct cell outline and difference due exclusively to mechanical influences. In the sections examined it has been noted whether each factor is absent, or present in slight, moderate, or marked degree. All points were then considered and the relative weight attached to each; the tumour was then placed in one of the following three groups:—

Group 1. Of slight degree of malignancy.
Group 2. Of moderate malignancy.
Group 3. Of marked malignancy.

In all cases the tumour was placed in the appropriate group before reference was made to the subsequent clinical history.

The following fallacies suggest themselves:—

(1) Different parts of the same tumour may show varying histological appearances. This should be guarded against by examining a sufficiently large portion, preferably cut from the periphery, where active growth is taking place. With this precaution the objection should not be valid, and, in fact, in those instances in which two different portions of the same tumour were available, both have always been placed in the same group.

(2) The histological appearances of metastases may differ widely from that of the primary growth, so that one should base the estimate of malignancy on sections from the primary growth alone.

The criteria of the degree of malignancy which have been adopted are, therefore, signs of rapidity of growth and of the extent of departure from the structure of the fully developed epithelium of the breast.

Material Investigated.

The present series consists of 50 cases, all of which were submitted to a radical operation between the years 1919–23 inclusive. The operations were performed in each case by the same surgeon, as it was thought that this would obviate discrepancies dependent on varying operative techniques. Only those cases were taken in which a sufficient clinical history was available and microscopical sections had been preserved, and in which the results were known up to the end of 1926. The minimum time since operation is therefore three years, and the maximum seven years. The records of cases during the war years were in many cases deficient, and the tracing of patients operated on before the war was found to present too many difficulties to be of value.

Results of Investigation.

If the cases are subdivided into groups according to the histological index of malignancy determined as above, there are:—

GROUP 1.—Slight histological malignancy, 16 cases.

Alive and well	11
Died of recurrence	2
Died following operation	1
Died of other causes	2

GROUP 2.—Moderate histological malignancy, 12 cases.

Alive and well	5
Died of recurrence	6
Died of other causes	1

GROUP 3.—Marked histological malignancy, 22 cases.

Alive and well	5
Died of recurrence	17

Thus there does appear to be a progressive deterioration in the results as the histological index of malignancy increases. This supports the conclusions of Greenough, who found:—

Group 1	68 per cent. of cases were cured.
Group 2	33 " " " "
Group 3	0 " " " "

The chief difference between the latter's figures and those recorded here is that, in the highest degree of malignancy he found no "cures," whereas in Group 3 of this series 5 cases out of 22 were alive and free from recurrence at the time of the investigation.

Since the above figures show that there is some relationship between the degree of malignancy estimated histologically and the subsequent course of the disease, it is next necessary to consider in what cases the criteria mentioned are of practical value in prognosis. To study this question the material has been subdivided into three tables (A, B, and C).

TABLE A.—*Cases Operated on before Axillary Involvement.*

Histological group.	Cases.	Alive and well.	Died of recurrence.	Died other causes.
1	8	7	0	1
2	4	4	0	0
3	5	5	0	0
Total	17	16	—	1

The analysis shows: (1) A relative preponderance of cases of slight or moderate malignancy. (2) A uniformly good result whatever the grade of malignancy. (The term "good result" is used in this paper as indicating the result within the time limits of the investigation.)

In other words, the less malignant a tumour the greater the chance that it will be treated in this early favourable stage, but should a more malignant tumour be operated upon adequately at this stage the result will be equally good.

In Table B are given advanced cases showing ulceration, fixity to pectoral fascia, adherent axillary glands, &c., in which operation was undertaken purely as a palliative measure.

TABLE B.—*Advanced Clinical Cases.*

Histological group.	Cases.	Alive and well.	Died of recurrence.	Died other causes.
1	3	1	2	0
2	3	0	2	1
3	9	0	9	0
Total	15	1	13	1

The analysis in this case shows: (1) A preponderance of cases of the higher grades of malignancy. (2) A practically uniformly fatal issue except in one patient with a low histological malignancy.

In other words, when this stage is reached the time for a "cure" has passed for the vast majority of cases, whatever the histological picture may be. Occasionally, however, as in one case in which a palliative operation three years after the tumour appeared was followed by three years of comfortable life, a low histological index may be associated with a more chronic course than would otherwise be expected.

So far, then, the histological features have not added much of value to the clinical data on which a prognosis is based, though demonstrating some facts of interest. It is in the intermediate type of case that they would be expected to be of greater value (Table C).

TABLE C.—*Intermediate Clinical between those of Tables A and B.*

Histological group.	Cases.	Alive and well.	Died of recurrence.	Died cause not known.
1	5	3	0	2
2	5	1	4	0
3	8	0	8	0
Total	18	4	12	2

The analysis shows: (1) That the only four cases known to be alive and well at the time of inquiry

HISTOLOGICAL CLASSIFICATION OF BREAST TUMOURS.

Group I.—Slight Malignancy.

FIG. 1.

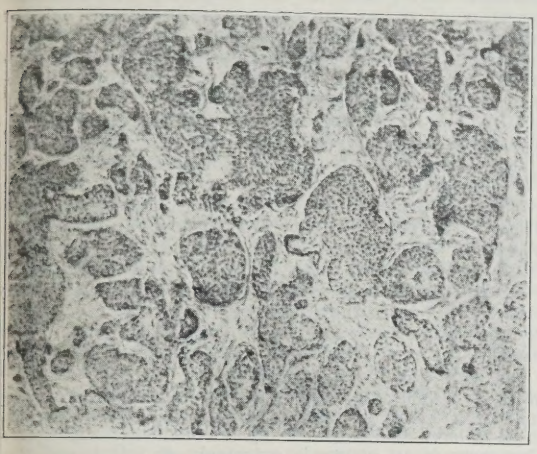

FIG. 2.

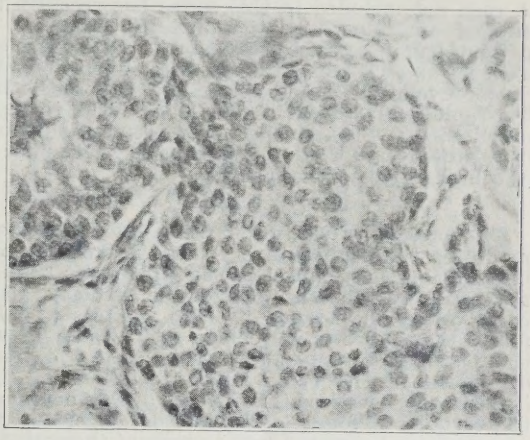

Tubule formation; cells even in size and staining.

Group II.—Moderate Malignancy.

FIG. 3.

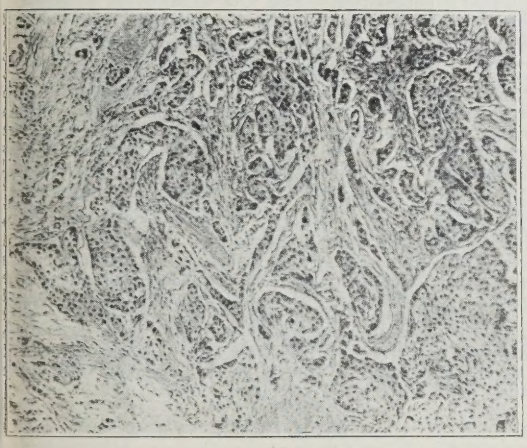

FIG. 4.

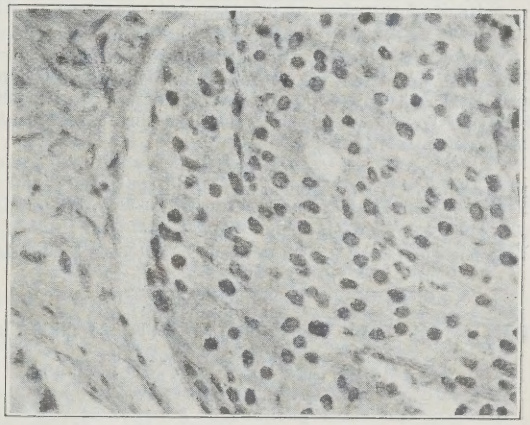
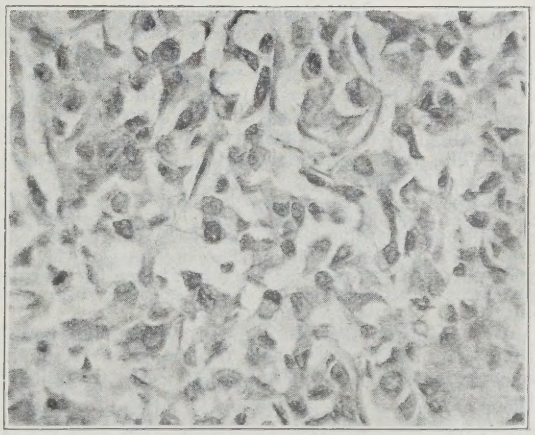


Absence of tubule formation; cells slightly uneven in size and staining.

Group III.—Marked Malignancy.

FIG. 5.

FIG. 6.



Irregularity of growth; absence of tubule formation; cells markedly uneven in size and staining.

These plates are given as examples of the groups into which the breast tumours have been classified.

belonged to the lesser groups of malignancy. (2) That all the cases of high malignancy died of the disease.

If, therefore, one should operate on a patient in whom axillary involvement is early, a favourable histological picture is of definite prognostic importance. A case not included in this series has recently been studied and illustrates the opposite feature. This patient had a small breast tumour with very early axillary involvement. Shortly after operation recurrence developed, and death ensued 18 months later. The rapidly unfavourable result was difficult to explain on clinical grounds, but became more explicable when it was discovered that microscopically the tumour was of a high degree of malignancy.

Conclusions.

The present study, even when due allowance is made for the comparatively small number of cases, in addition to confirming the prognostic value of microscopical examination of the axillary glands, corroborates the results of those workers who have found that there is a definite relationship between the histological appearance and clinical course of carcinoma of the breast. This relationship shows itself in three ways: (1) In cases of low malignancy the early or favourable stage is of longer duration, and patients are more likely to present themselves for treatment before there has been much spread of the disease. (2) In advanced cases palliative operation tends to be followed by more prolonged benefit if the histological index is low. (3) Histological estimation of the degree of malignancy is of value in prognosis in a limited number of intermediate cases—i.e., those in whom axillary involvement is early.

We wish to express our indebtedness to Mr. Sampson Handley, surgeon to the Middlesex Hospital, and to Prof. James McIntosh, director of the Bland-Sutton Institute of Pathology, for direction and assistance in this work.

PROGNOSTIC TESTS IN TUBERCULOSIS.

BY B. L. MCFARLAND, M.D.,
M.CH.ORTH. LIVERP.,
ASSISTANT HONORARY ORTHOPÆDIC SURGEON TO THE ROYAL LIVERPOOL CHILDREN'S HOSPITAL.

THE object of this work was to investigate the value of certain tests applied to pulmonary tuberculosis. The comparative facility with which the stage and progress of the disease can be estimated in so-called "surgical" tuberculosis suggested that a large number of such cases might be used to standardise the tests. The following were selected: (1) a modification of Erhlich's diazo-reaction, called the urochromogen reaction; (2) the Arneth[1] count of lecucocytes; (3) the degree of cutaneous pigmentation; and (4) the quantitative von Pirquet cutaneous test. The urochromogen reaction (U R) was described by Weiss[3] in 1911.

Into each of two test-tubes is put 1 c.cm. of urine, and 2 c.cm. of distilled water are added. To one tube are added three drops of 1/1000 solution of potassium permanganate, and the mixture is shaken. The presence of the faintest yellow (compared with the control) is taken to indicate the presence of urochromogen. The test is read as positive only when the mixture remains clear.

In comparision with similar tests, this has been found the most useful and delicate.[4 5 6] With a few exceptions [7] it has been applied only in pulmonary tuberculosis.

The cases investigated in the following series were all children under the age of 16. Their tuberculous lesions were non-pulmonary, and they were in-patients at the Liverpool Open-air Hospital at Leasowe. They were examined clinically every month as a routine, and more frequently if indicated. The urines were tested for urochromogen once every month, and if positive were tested every week or fortnight. It was found useful to have a second control consisting of normal urine, and in the majority of cases the proportion of urine to water was increased. It is essential that the potassium permanganate solution be freshly prepared. The test must be done in daylight, as slight colour changes are not apparent in electric light. The degree of intensity of the reaction was judged by the naked eye. For the purposes of comparison, urines from 152 cases in the medical and surgical wards of a general hospital were tested for urochromogen. Two gave a positive reaction, one a case of pneumonia, the other a case of diabetes mellitus. The reaction was proved to be independent of common abnormalities in urine. The work of Addis [8] in connexion with blood pigments suggested that urobilinogen might be responsible for the colour change. This was disproved.*

Recent investigations have suggested that there is some connexion between the urochromogen test and the van den Bergh reaction.

At Leasowe 360 cases were followed for periods of four to ten months. Thirty-six had a constantly positive reaction. Of these 22 have died within two years of the investigations; the recovery of 10 others is extremely doubtful, and the remaining 4 are undecided. In a year there were 12 deaths. Of these 7 had had a constantly positive U.R.; in 2 others the reaction had turned from negative to positive. The remaining 3 were proved, post mortem, to be non-tuberculous. One with extreme cachexia was thought to be suffering from miliary tuberculosis, and the absence of a positive reaction was inexplicable until the autopsy, when death was found to be due to diffuse sarcoma of the abdomen, the primary lesion being in the ovary. Eighteen cases out of 360 gave a positive reaction of slight degree and of short duration. In 6 of them a definite exacerbation of the disease was demonstrated, although in none did a change in the general condition occur. In 11 cases the reaction changed from positive to negative. In 2 others there was a marked decrease in the intensity of the reaction. In all of these there has been considerable improvement in general condition, and in 8 an arrest of the local disease. In 2 old-standing cases the improvement in general condition was in advance of the decrease in positivity. Eight cases changed from negative to positive, and in all these the change was followed by a decline in general condition and either the appearance of a fresh focus or an increase of the original one. In most of them the change in the reaction preceded the other manifestations by about a month. The rest of the 360 were all negative. Of these 4 seemed to have advanced and severe tuberculosis, but a good prognosis was given and they have since improved enormously.

Blood Films.

In examining the blood in films, an ordinary differential white count was combined with an Arneth count of the polymorphonuclear leucocytes. Some preliminary work was done with a view to forming a standard interpretation of the number of the lobes. 120 blood films were examined. In ten cases films were taken every month, concurrently with the urines. A few normal children were used as controls. In the hopeless cases—e.g., those with amyloid disease—the average count was:—

(1)	(2)	(3)	(4)	(5)
40%	39%	16%	5%	0%

Arneth index† = 87.

In those cases quiescent, or nearly so, the average count was:—

(1)	(2)	(3)	(4)	(5)
6%	33%	43%	16%	2%

Arneth index = 60·5.

The average count in the controls was:—

(1)	(2)	(3)	(4)	(5)
4%	34%	41%	19%	2%

* Thirty urines giving a positive U.R. were tested for urobilinogen (Schlesinger's test). Three gave a positive reaction. All the urochromogen was converted to urochrome (excess of potassium permanganate), which normally occurs in urine, and the test for urobilinogen was still positive. Two of the urines which gave a negative U.R. gave a positive urobilinogen reaction.

† Arneth index is obtained from the formula:—

$$(1) \text{ plus } (2) \text{ plus } \left(\frac{3}{2}\right).$$

Of the cases taken monthly, four showed marked clinical improvement, reflected in the blood picture by a gradual move to the right. In very bad cases there were practically no eosinophil cells; in the quiescent cases there was a normal or high percentage. In the cases improving rapidly there was an eosinophilia of 6 per cent. to 8 per cent. The eosinophilia will be the subject of a separate communication.

Pirquet Skin Reaction.

An endeavour was made to demonstrate any relation there might be between the activity of the disease and the rapidity and intensity of the reaction. The technique described by McNeil [11] was modified slightly. Koch tuberculin A (undiluted), human and bovine, were used with normal horse serum as a control. The reactions were watched for three weeks, and 200 Pirquet tests were done. There were 12 negative results (tests repeated). All cases giving a positive reaction with human T.A. were positive with bovine. Four that were negative with human gave a positive with bovine. A positive may be read in any time from a few minutes to a few days. A negative can only be decided by waiting three or four days. A reaction to the horse serum always disappears within five days. The stage or severity of the disease was found to bear no relation to the intensity, duration, or rapidity of the reaction. Even a child giving a negative result is more or less a clinical curiosity.

Pigmentation.

Rollier [2] and others [14] have pointed out the connexion between quiescence of disease and the pigmentation of the skin in response to heliotherapy. It was found in this series that cases with severe and progressive lesions did not form pigment, and these sandy hair and freckled type) had poor resisting powers. Favourable and quiescent cases became very brown, but a few of them subsequently relapsed. Cases with amyloid changes show a dislike and intolerance for sunlight, just as do the cases of congenital hæmatoporphyrinuria mentioned by Garrod.[9]

The intolerance of light by children with amyloid disease is confirmed by the work of J. V. Supniewski (*Journal of Physiology*, 1927, lxiv., 30), who investigated the action of physical light on organs sensitised by hæmatoporphyrin. He found that the heart, intestines, and uterus went into tonic contractions. There was a rise of blood pressure and death.

Conclusions.

It was definitely concluded that none of these tests is sufficiently delicate to differentiate between a case in which the disease is mild but active and one in which it is quiescent.

It was decided that although pigmentation is a favourable sign, it is no guarantee of inactivity.

The severity, rapidity of onset, and duration of a standardised Pirquet cutaneous reaction do not bear any relation to the severity or stage of the disease.

There is a gradual return to a normal Arneth count as a lesion becomes quiescent. There is a tendency towards normal after heliotherapy and a reversion during the winter months.

The relative percentage of lymphocytes has not been found to have any significance.‡ The presence of eosinophil cells in more than 3 per cent. or 4 per cent. is a favourable sign.

The urochromogen reaction is always present in severe cases or in late stages of the disease, when the variation in the intensity of the reaction is of value in prognosis. Its absence in an apparently severe case is a reliable indication that the defences of the body are adequate for the time. Its presence in an apparently mild or quiescent case is a very valuable indication that the disease is progressing and that the defences of the body are inadequate. Its appearance for a short time during the acute stage is not of serious import.

‡ That is to say that, in this series, the relative percentage of lymphocytes (large and small) was of no value in differentiating cases with regard to the stage of the disease (see table).

—	Urochromogen reaction.							Blood films.

Clinical conditions: (A) Non-tuberculous. (B) Quiescent. (C) Active but uncomplicated and favourable. (D) Favourable cases becoming complicated. (E) Serious cases showing marked improvement. (F) Persistently serious cases.

* Non. T.B. † Two less +ve.

The conclusions of previous workers have been confirmed, except when they say [4] that cases which show a persistent positive reaction in spite of treatment have a hopeless prognosis. Five cases had a positive U.R. for seven months at least, but they have since improved and the test has become negative. Dehoff's statement, that it is of use to a surgeon whose beds are limited in selecting cases for treatment, has not been confirmed, as a single positive reaction is of no value. It would be unwise to reject a case as hopeless on such grounds; the test would be of more value to a surgeon supervising cases discharged as quiescent, for the appearance of positive U.R. nearly always precedes any appreciable change in clinical condition.

EXTENSION OF CHARING CROSS HOSPITAL.—At the annual general meeting it was stated that the hospital has now not only obtained possession of the adjoining premises of the Royal Westminster Ophthalmic Hospital, but has obtained them free from debt, the generosity of the public having provided the £70,000 required. A further £30,000 has yet to be raised for the equipment of the new premises, and it is desired to buy a site for a nurses' hostel.

STREET ACCIDENTS AT NORWICH.—The annual report of the Norfolk and Norwich Hospital states that the recent extensions have proved insufficient to meet the demands. A serious contributory cause of the failure is the large number of street accident cases. On one occasion during the past year there were 32 motor accident cases in the wards. The average length of stay of these 32 patients was 86 days, whereas the average length of stay of all patients was only 21 days. There has consequently been a very large increase in the waiting list.

THE INJECTION TREATMENT OF VARICOSE VEINS.

AN ESTIMATE OF ITS PLACE IN PRACTICE.

By RODNEY MAINGOT, F.R.C.S. Eng.,
SURGEON, ROYAL WATERLOO HOSPITAL;
AND
C. HOPE CARLTON, F.R.C.S. Eng.,
SURGICAL REGISTRAR, ROYAL WATERLOO HOSPITAL.

THERE are few conditions more commonly seen in a surgical out-patient department than varicose veins, which handicap a large section of the adult population by the pain and disability which they cause. Surgical excision is time-honoured but time-consuming; its application is limited and its results uncertain, while dangerous complications are by no means rare. The authors of this paper have read with interest the writings of Sicard,[2] Meisen,[3 4] and Douthwaite,[1] and have applied their methods in several hundreds of cases. The aim of this article is not to deal exhaustively with the subject, but to set forth in essential detail those applications of the method of varicose vein injection which undoubtedly relieve the patient. While the authors acknowledge the debt they owe to the pioneers in this field, it is their intention to set forth only those facts which have been abundantly demonstrated in their own practice.

Solutions Used.

In this series the two following solutions alone were used:—

1. Sodium salicylate, 25 per cent. } in equal parts.
   Sodium chloride, 10 per cent. }
2. Quinine bihydrochloride (or hydrochloride), 4 g.
   Urethane, 2 g.
   Distilled water to 30 c.cm.

These solutions must be freshly prepared and sterile. Should the quinine have crystallised out, the solution must be raised to boiling-point in a water-bath before use. Ampoule preparations are not recommended as it is doubtful whether they will keep. The best container for the solution is a conical glass flask plugged with wool, or a glass-stoppered bottle.

It is difficult to choose between the quinine and the salicylate solutions; in fact, some patients may best be treated by the injection of one drug in one part of the limb and the other in another part. In general, we recommend the sodium salicylate when the veins are large and covered with healthy skin. The quinine-urethane is the less powerful venous obliterant, but is advisable when the veins are small, the patient apprehensive, or the operator gaining experience.

Technique.

The injection operation must combine simplicity with strict asepsis. It is carried out as follows.

The patient is seated on a gynæcological chair or on an ordinary operating table, one end of which is raised as a back rest and the other allowed to hang down behind the patient's dependent legs. The feet may rest upon a stool. In this position the knees are bent at about a right angle and the whole lower extremities are abducted about 40 degrees. When the veins are situated posteriorly the patient stands upon a broad-based stool. In front of him is an assistant upon whose shoulders he leans for support. The operator sits behind him on a low chair. Should the patient feel faint—which is possible, but rare—the assistant can support him and help him to lie down.

The skin is cleansed with spirit; no coloured antiseptic can be used as it would mask the veins. The area of operation is isolated with sterile towels. A tourniquet is unnecessary, painful, difficult to handle, and increases the bleeding by augmenting venous congestion.

The injection is made with a 5 c.cm. Record syringe to which is fitted a fine hypodermic needle; both are sterilised overnight in spirit and are rinsed in sterile water before use. The needle of the charged syringe is inserted through sound skin and pushed on through healthy tissues for a centimetre. It is never allowed to pierce the vein directly; the point must always traverse sound skin and healthy connective tissue before entering the vein. In this way a valve-like puncture is produced, and post-operative backflow extravasation is rendered unlikely. It is this backflow which produces post-operative pain, discoloration, and patches of necrosis leading to ulceration.

The next step is for the operator to satisfy himself beyond any doubt whatever that the point of the needle is actually within the lumen of a vein. When blood appears in the syringe on withdrawing the plunger the injection is proceeded with. The fluid should be injected at the rate of 1 c.cm. in 5 seconds. A faster rate may cause painful spasm or even rupture of the vein. If pain is caused the needle is withdrawn and inserted at another point. As a general rule the injection is made in the direction of the blood flow, which is from the trunk toward the extremities when the limbs are vertical. The amount of fluid introduced at each puncture varies from ½ to 5 c.cm. according to the size of the vein. No more than 15 c.cm. should be given at one sitting. As a rule, three sittings are necessary for each patient; fewer may suffice to produce thrombosis in small varices, and more may be necessary for very large tortuous veins involving a whole limb.

A piece of adhesive strapping the size of a postage stamp seals the puncture when the needle is withdrawn. If several punctures have been made, a crêpe bandage or a flannel bandage cut on the bias is applied, to give comfort, protection, and support.

After the operation the patient is encouraged to walk about the room and advised to continue his usual occupations, although violent exercise should be avoided for a week. Post-operative elevation of the limb is definitely contra-indicated.

Results and Effects.

The general effect is most gratifying in the majority of patients. Often they are so pleased that they want to have more injections at once, although prudence advises the operator to wait for the results of the first treatment before proceeding. The increased sense of well-being is especially marked in women whose handicap has been so great as to make them do as much of their housework as possible sitting down with their legs up. Most of those treated have returned to work and continued in active occupations.

Among the general ill-effects noted in this series are giddiness, fainting, tinnitus and, in women, general abdominal pain, especially after quinine.

After a successful injection the vein sometimes dilates, but usually contracts and loses its blue colour immediately. An hour later it is once again prominent. On the succeeding day it is hard and thrombosed to an extent which varies directly with the amount of solution injected. There may be a feeling of fullness, but this passes off on walking about. The limb may be stiff for a few days, but this, like the cramp and joint pains of which patients often complain, passes off. The limb diminishes in size and its natural contour is restored, and after six months only the fibrous strands of the veins remain. These strands are most easily felt and persist longest over the subcutaneous surface of the tibia; they disappear rapidly where they are supported by muscle, as in the calf.

Some patients complain of a burning sensation at the time of injection; the solution—especially sodium salicylate—must not be injected too forcibly or pain and severe cramp may result. Fully half the patients complained of tenderness of the limbs for several days after operation. This is no doubt due to a mild inflammation concurrent with obliteration of the lumen. About 10 per cent. of patients showed discoloration or pigmentation round the area of injection. This may take months to disappear, and is probably due to perivenous leakage as it occurred most commonly in those cases which bled at the time of injection.

Complications.

Complications are generally due to neglect of the technique described in this paper—e.g., faulty preparation of the solution or lack of ordinary aseptic and antiseptic precautions.

In this series the only cause of failure was non-entry of the fluid into a vein, which may lead to discoloration, inflammation, or actual ulceration (two cases in our series). The technique of perivascular injection has been described by some writers,

but the authors do not recommend it, except for minute skin varices.

Mild degrees of shock and collapse are fortunately uncommon, but need mention. Douthwaite and others have suggested that this important complication may be avoided by previously testing the patient with small injections.

Embolism is exceedingly rare, although one fatal case has been recorded by Olsen.[7] It is far more frequent after surgical excision.

Acute septic phlebitis, acute cellulitis, and acute local suppuration have all been recorded and are presumably due to an infection at the time of operation. Ulceration and local gangrene may result from extravasation of the fluid, and there may be an extension of an existing eczema.

Contra-indications.

Quinine is contra-indicated in pregnancy, owing to the risk of abortion, and causes hypogastric pain and faintness during menstruation. Injection treatment has no place in advanced renal, cardiac, or pulmonary disease, nor when there is obvious high blood pressure. It is contra-indicated by deep thrombosis in the leg, which may be suspected if one leg is larger than the other, or if there is constant œdema or a history of deep lymphatic thrombosis or of acute white leg after pregnancy or typhoid fever. Acute septic thrombo-phlebitis of the superficial veins at the time of examination would negative injection treatment until the inflammation had subsided. Idiosyncrasy to quinine or salicylate must be kept in mind.

Varicose Ulcers.

There is no specific cure for varicose ulceration, and some patients respond to one treatment and some to another, while a few remain intractable to all. These latter suffer from ill-health, poor physique, and low resistance. The technique followed by the authors of this paper is as follows :—

> The ulcer is first cleaned up with fomentations or hypochlorite dressings. If the patient can afford the time he is kept in bed until the ulcers have healed and the veins are then injected, but if not the two remedies are applied simultaneously. Patients who insist on continuing their work can often be successfully treated as ambulants.
>
> The secret of success lies in the four words : Unna's paste properly applied. The patient is seated, with the leg horizontal and the feet on a stool. Unna's paste warmed to the consistency of cream is painted in a 3-inch zone around but not over the ulcer. A book-muslin bandage soaked in water is then applied from the toes to the knee and painted over with the paste. A second bandage is then applied and painted and the two are covered with a flannel bandage cut on the bias to conform to the contour of the leg. After ten days the paste stocking is removed, and the ulcer will be seen to be healing. The veins are injected at this stage and another Unna's paste bandage applied. From this time the cure of the veins and that of the ulcer go hand in hand.

Skin-grafting after excision has been used with success for small ulcers. Strapping the leg from ankle to knee with zinc oxide plaster in overlapping strips is sometimes useful ; the strapping is placed directly on the surface of the ulcer. The authors do not recommend X rays or ultra-violet rays, nor have they found endocrines or calcium chloride of much value. No success has followed infiltration of the base and edge of the ulcer with quinine. When the patient has a positive Wassermann reaction the arsenical injections may well be given into veins adjacent to the ulcer.

Conclusions.

The aim of this paper is to encourage others to apply a method, the value of which has been so well proved in clinical practice as to make it the treatment of election. It is simple, inexpensive, time-saving, and comparatively free from complications. Its value to the State is shown by the reduction it could effect in disability under the National Health Insurance Act and in rendering candidates eligible for the Services. Its value to the individual is demonstrated by the appreciation of those on whom it has been used. Recurrence does not occur, at any rate within the three years' experience on which this paper is based.

Clinical and Laboratory Notes.

A NOTE ON CUTANEOUS AND VISUAL HALLUCINATIONS IN THE CHRONIC HALLUCINATORY PSYCHOSIS.

BY E. D. MACNAMARA, M.D. CAMB., F.R.C.P. LOND.,

PHYSICIAN FOR MENTAL DISORDERS, CHARING CROSS HOSPITAL, AND PHYSICIAN TO THE WEST END HOSPITAL FOR NERVOUS DISEASE.

HALLUCINATIONS as is implied in the name of this syndrome constitute its most outstanding characteristic. They are obsessive, compulsive, and lasting. Patients do not, except possibly in the earliest stages, recognise the hallucinations as due to the morbid states of their own minds. The symptoms, by reason of their unpleasant nature and the fatiguing conduct which they occasion, are followed in some persons by mental obfuscation and slight confusion. Beyond this there is little or no mental disorder, and patients remain of normal affections, properly orientated, of good powers of judgment, choice and reaction in such affairs as are apart from their hallucinations. The annoyance caused is not set down to the persecution of enemies. Patients present, so far as can be discovered, no signs of toxic or endocrine disorder.

The hallucinations as described in literature are auditory and I have nowhere found accounts of other sorts. I propose to give in the following abstracts of notes instances of cases in which hallucinations have been first cutaneous and secondly visual.

Description of Five Cases.

CASE 1.—A. B., aged 60, single. This patient was first seen in July, 1921. She complained of things moving about the skin and that "black things came out of the skin." She produced a pill-box containing cotton, fluff, and debris said to have come out of the skin. The feelings were constant and interfered much with sleep. She spent much time hunting for "the things" in her bed and, having captured them, she placed them in water, where she saw them wriggle. This state of affairs had lasted for years. She displayed some signs of anxiety. Her look was one of constant worry. She occasionally caught at her breath and complained of suffocating feelings. She asked if the things on the skin were alive and if they could be given to other people. Her history revealed nothing relevant. The skin showed no lesion except a few marks of scratching. From July, 1921, till January, 1924, the patient did not attend. She then said that at night she had to rub her skin and that black things thereupon came from it. The things had wings. The next attendance was in February, 1927, when she brought a box containing small feathers and bits of thread, which she said had come out of her skin.

In September, 1927, she complained that lumps came out on her face, and that microbes which she could seize ran over it. Her clothes, she said, were full of black insects. She brought with her some tea-leaves which she said came from her skin after the applications of lotion. No amount of argumentation or demonstration could shake the patient's belief as to the truth of her allegations.

CASE 2.—C. D., aged 61, single. First attended in May, 1927. Complained of irritation and rash of the scalp and upper part of the body. Insects about the size of a flea walked under her skin and came out from it. Nobody except herself saw them. They were first noticed three years before. The patient spends many hours each day attending to herself, "rubbing the skin with bread-crumbs to bring out a rash." She gets up at night to look for insects. She ceased work a year ago in consequence of her condition. There is a slight degree of dermatitis, apparently due to the over-vigorous treatment applied to herself by the patient. There is no relevant personal or family history. She cannot be persuaded that there are no insects about her.

CASE 3.—E. F., aged 64, married. First attended in June, 1927. She said that for four months before she had on four successive days washed and brushed her dog, who had lice. Through doing this she had got lice herself. She has since then seen little tiny black things over her face, which constantly irritate her by crawling about. Ever since she has daily washed her clothes with chloride of lime and herself in sulphur baths. The dog and cat have been killed. There was nothing abnormal to be seen and she could not be persuaded that she had no parasites. There was no relevant personal or family history. At later attendances she said she was a little better and had not seen so many insects. She still felt them and, about the middle of the day, "they came like a swarm."

CASE 4.—G. H., aged 44, single. First attended in July, 1927. In 1922 she had taken some children to a circus and "one of them afterwards got some lumps." The patient then began to notice tiny black things, like powder, in the bed, and on rubbing her skin with ointment, tiny things came out of it. In a hot bath she feels an intense pricking sensation, and on rubbing herself "hears things clicking." She thought she had infected other people, including her sister and the maids in a house where she had been staying. In consequence of her condition she has done no work for about 18 months. She was convinced as to the reality of the existence of a parasite.

CASE 5.—I. J., aged 42, single. This patient is a sister of G. H. Her symptoms began four years ago and after the commencement of the disease in the sister. She attributes her sister's affection to her having slept in a bed which had been occupied by a man who had died of a tropical disease. She says that the sister's affection commenced a year after this occurrence. Extracts from the patient's written description run as follows: "Irritation everywhere and burrows or bites . . . we had to cut our hair off six months ago on account of a tiny black-and-white insect fine as dust that infected the head and sprang into the eyes, nostrils and ears from the hair. . . . I sometimes noticed a brown linseed-like thing that split open and had a thread hanging out. My ears were in a terrible state of pain where they had been burrowed some time back . . . the head seems to be the most infected with this trouble. One feels things too small to be seen flick all over us." No skin lesion or parasites were to be seen, but the patient could not be convinced that this was the case. There was no relevant personal or family history.

Commentary.

In these cases commonplace itching seems definitely to have preceded the morbid mental state and to have unduly excited and riveted attention. To explain the sensation, the reputed ways of parasites are remembered and fastened on by a mental disposition of a hypochondriacal type, just as in other hypochondriacal states banal abnormal feelings, such as flatulence or palpitations, are attended to and made much of. With heightened attention comes imagination awaiting the realisation of that which is expected. Talk about cutaneous parasites, or something read about them, is remembered and the imagination gradually materialises itself in the outside world. Material from sebaceous glands, bits of fluff, hairs, crumbs, tea-leaves, etc., become in the patient's mind parasites, and are endowed with particular properties and at length are seen to move. Perceptual processes involve the exercise of mental functions, such as the affections, selection from the environment of particular objects for attention, memory for purposes of comparison, imagination, reasoning, usually implicit, but occasionally explicit, and due balance between these functions. Text-book definitions of abnormal perceptual processes, though useful, suggest too hard and fast a differentiation from delusions. Hallucinations involve errors in processes of judgment and reasoning. If perception may be regarded as the intellectualisation of sensation or, more colloquially, the thoughtification of things, the error may be held to be of a delusional character probably arising from the vitiation of the perceptual processes by some strong uncoördinated affect, manifesting itself in the perceptual rather than the conceptual field.

Owing to the firm belief of patients in the existence of their parasites, various lines of conduct are adopted. Patients tend to withdraw themselves from contact with others, and some reach a stage of almost complete seclusion. Washing, scrubbing, fine-combing, and picking may be carried on till the patient is exhausted, and may reach a point at which dermatitis is caused.

Treatment is unsatisfactory since all that patients desire is some agent which will kill the parasites. They do not agree with the physician that psychological treatment is necessary. It is nevertheless curious that such patients remain content to attend an out-patient department for psychological medicine, as if there was some slight glimmering at the back of their minds that their trouble is "nervous." G. H. and I. J. show that rare phenomenon *folie à deux*. I. J., as the story runs, was infected by G. H., and at any rate shows her hallucinatory ideas and ways of re-acting to the supposed situations.

A NOTE ON CAMPTOCORMIA.

BY G. F. WALKER, M.D. LEEDS, M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, GENERAL INFIRMARY, LEEDS.

CAMPTOCORMIA is a neurosis occasionally seen in civil life. It was relatively common during the late war, especially among the Latin races, and there is an abundant French and Italian literature. The malady is the assumption of a gait and posture described by Hurst as resembling that of a stage octogenarian. The body is bent forward at the hips; the shoulders are braced backwards; the head is lifted by extension of the cervical spine. The patient peers upwards and forwards, grinning with fatuity. There are concomitent functional coarse tremors of the head and arms and shaky weakness of the legs with slight knee flexion. On getting the patient to repose on a flat table, both the dorsilumbar flexion and the cervical extension disappear.

This curious malady was described fully by the French neurologists, Joltrain and Souques, in the early part of the war. It was rediscovered again and again by French, Italian, British, and American war neurologists, and among the best accounts is that of Hall. Joltrain's original case was that of a soldier who was buried by earth and debris, so that he experienced acute flexion of his whole spine, partly from "ducking" and partly from debris falling on his back. He was extricated in a terrified condition and was found to be unable to straighten his back. He remained in the hunched-up position for two and a half days, at the end of which time a functional paraplegia suddenly appeared. There was no organic, nervous, or bony disease and treatment restored him to normalcy. Joltrain likened the posture of dorsal flexion with an alert peering head extension to that of a gamekeeper's dog.

From about 50 case records since Joltrain's original paper it is clear that the ætiology varies widely. Trauma to the spine directly or indirectly, emotional shock, and long-standing exhausting fevers all seem capable of provoking the malady. Anon set in a workman after an accident is described by Hurst as "not very rare." The patients are of neurotic stock and there is no organic disease.

One form of treatment was described by Hall. The patient is stretched out on a flat board like a butterfly on a show-card and kept in that position for about 18 hours of the 24. He is securely fastened, and board and patient are bodily moved about from time to time in various planes. A good deal of the 18 hours is at first spent in the prone position, but gradually more and more time is spent in the vertical position. Muscle re-education and massage are carried out at intervals. To get the patient on to his board or frame in the first place an anæsthetic may be necessary. A totally different treatment, by psycho-analysis, was carried out in many war cases by Mme. Rosanoff-Saloff in association with Souques. The prognosis as to complete rehabilitation of the patient would seem to be very good, but many months may be required.

FIG. 1 (Case 1).

I am indebted to Dr. le Fleming Burrow and Dr. William MacAdam, of the honorary staff of the General Infirmary at Leeds, for permission to record the following cases :—

CASE 1.—R. B., aged 35. Is a miner in a poor district, oppressed by vicissitudes. He was first seen in October, 1927, and Fig. 1 is reproduced from a photograph taken at that time. He waddled into the out-patient department smiling happily, but with his trunk heavily flexed forwards. He explained that he was "always a nervous chap," and had been invalided out of the army for shell-shock in 1917. His reason for seeking advice was a diffuse backache, and particularly inability to "straighten out." The disability was of 12 months' duration and followed a long and severe attack of influenza. He had had no injury. He complained of difficulty in walking on account of his backache and flexion, but he gave his history with happy zest. The site of the pain was mostly in the lumbar column, and palpation there caused immediate full spinal extension with quick resumption of the bent forward attitude after a few seconds. He took up a prone position on a couch quite gaily and easily, and when the examination was finished he jumped briskly to the ground. General and radiological examination was quite negative for organic disease, and re-education by various methods brought about relief.

FIG. 2 (Case 2).

CASE 2.—K. S., aged 32. Described himself as "neurasthenic for years." Had suffered from shell-shock. In April, 1927, he fell ten feet from a scaffold and "landed" on his back. He was in bed for 14 days on account of pain and bruising. On getting up he found himself unable to "straighten out." A radiological examination and general physical examination did not disclose organic disease. He conformed very closely to Hurst's description of the "soldier walking painfully and slowly with the aid of two sticks, bending far forwards, his arms and legs often shaking with the effort, for all the world like a stage octogenarian." Fig. 2 is from a photograph taken at the time, but the blissful grin cannot be reproduced, in deference to the patient's wishes. He is getting better under a régime modified from that of Hall.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

A MEETING of this Section was held on April 3rd, with Mr. W. ROWLEY BRISTOW, the President, in the chair, to discuss the

OPERATIVE TREATMENT OF RECENT FRACTURES OF BONE.

Dr. CHARLES SCUDDER (Boston, U.S.A.) read the opening paper. He said that the subject was important for several reasons. The whole patient was damaged, as well as the bone; it was necessary to decide immediately on the course of treatment to be applied throughout, and unsatisfactory traditional and detached ideas of fracture treatment were very generally prevalent. Again, the initial treatment might stupendously affect the subsequent course of events and every general practitioner could understand and apply a simple, effective, primary treatment. The standard of result set 30 years ago was unsatisfactory to-day to the patient, his family, his employer, and the insurance agent. Moreover, the type of fracture had changed. There were more multiple fractures, more complicated joint involvements, and greater damage to bones and soft parts. The annual loss to industry from badly treated fractures was estimated at millions of dollars. The operative treatment of fractures, resting as it did upon the principles evolved by Lister, stood to-day on a fundamentally sound basis. Surgeons should strive more energetically for anatomical perfection which meant a nearer approach to functional perfection and the prevention of sequelæ due to inaccurate replacements. It was dangerous to advocate incomplete reduction in an adult; to live habitually in an atmosphere of surgical compromise was stunting to progress and likely to develop surgical cynicism. The desirability of anatomical reposition and the use of X rays called more and more often for direct operative approach. Bone was no longer regarded as a dry, inert, stable, terminal form of matter serving as the passive framework of the body. It was flexible, living, unstable, changing tissue—an active organ, intimately associated with the vital processes of the body and sensitive to all extraneous influences and events. It was a delicate tissue demanding great consideration and gentle handling. This view of bone emphasised the importance of immediate and exact reposition of fracture fragments, so that the reparative process would be least interfered with and ideal union accelerated. A fracture was an injury to a

complicated intelligent mechanism, and the recovery of the normal functioning of the whole organism was at stake. The will was involved in every fracture and influenced the recovery of function; the earlier the will coöperated in securing return of function the more rapid and complete was the recovery of the individual. There could be no rigid rule as to the time of union of a fracture, and the parts could be moved as soon as movement would not disarrange the replaced fragments. Absolute fixation by operation secured the minimum of callus necessary for sound repair, and allowed early movement without disturbance. Operative treatment of fractures was logical, natural, and had come to stay.

Indications for Operation.

Granted skilful surgery and anæsthesia and the necessary apparatus, the important indication for open operation was that it secured an earlier return to a more nearly normal function than any other form of treatment. This did not mean that every fracture should be operated upon. Operative advance should be safeguarded, and limited to skilled surgeons in hospital surroundings. Each case was a problem by itself, dependent on the exercise of the highest type of surgical judgment. The surgeon must have an adequate knowledge of the patient, physically, mentally, industrially, and socially, and of all the conditions. He must have perfect instrumental, mechanical, and physical equipment, an accustomed and proved technique, an understanding of the nature of bone tissue and its reactions, experience of both operative and non-operative procedures, and an open mind in selecting the one best adapted to the case in hand. No other surgeon should employ the operative method. The time to worry about the outcome of fracture treatment was in the first two hours after injury. Adequate immediate treatment would do much to prevent difficulties. Among fractures never operated upon were Colles's fractures, fracture of the clavicle, and many occurring in childbirth, childhood, and adolescence Fractures usually operated upon were fractures of the great tuberosity of the humerus with displacement, of the surgical neck of the humerus with dislocation, of the olecranon with separation of the small fragment, of the head or neck of the radius with sufficient displacement to limit movements, and of the shaft of the radius with displacement of the ulna. Most surgeons also operated upon separated or displaced epicondyles of the humerus or femur, certain elbow-joint fractures, and oblique or spiral fractures of the tibia and fibula, displaced fragments of the patella, irreducible fracture of the femoral shaft, fractures of the os calcis in which the line of fracture entered the astragalo-calcaneal joint, certain metacarpal and metatarsal injuries, and fractures about the ankle-joint which were difficult to hold. Operation was very doubtfully applicable for fractures of the spine with immediate symptoms of transverse lesion of the cord, fractures of both bones of the forearm, and of the humerus above the middle. Proper traction on the femoral condyles, tibial crest, or malleoli, or through the os calcis, might diminish the necessity for operation.

Almost any fracture of the neck of the femur entered the capsule, and the treatment of election was traction under general anæsthesia, with internal rotation, abduction, and hyperextension. Sixty per cent. of cases at the Massachusetts General Hospital had secured bony union by this method. There was no way of identifying the other 40 per cent. in advance, but careful study of the skiagram would show that the neck was being absorbed and that union would not take place. The second choice was the reconstruction operation rather than pegging. Cotton, of Boston, believed in artificial impaction instead of abduction. He put his stockinged foot into the injured groin and pulled until both legs were of equal length. Then, inverting the leg with the pelvis supported, he put a double piece of Sadler's felt over the great trochanter and hit it with a wooden mallet. His results were satisfactory. Delbet, of Paris, pegged practically all his adult cases and got union in 50 per cent. I another Paris clinic a bone-graft was placed on th neck of the femur with surprising accuracy by special piece of apparatus.

Advantages of Opportunism.

Sir ROBERT JONES (Liverpool) said he was please to note that though Dr. Scudder was, at the beginnin a strong advocate of the purely operative metho he yet encouraged perseverance with non-operativ measures. For himself, he did not like to feel that h belonged to any one "school," because he was sur the truth did not remain in any one of them, an probably not in all put together. So very muc depended on the surgeon who saw the case—on wha he could do and what he could do well. At one tim plating and wiring had been carried to extremes he had once removed a plate from a child 6 month old, and they had often had to be removed becaus they were beginning to give trouble after two o three years. This had led to a reaction to the othe extreme. Dr. Scudder said that in cases of fractur of the femur it was necessary to operate in order t secure perfect anatomical reposition. But everythin depended upon which was the good and which wa the bad type of union. In the femur end-to-en apposition was good, but if there was very sligh deflection it was bad. A slightly overlapping fractur if in good alignment, was a better result than a end-to-end apposition which had been allowed t cant to one side. He had seen cases in which platin had been done and this point had obviously not bee remembered. In the treatment of fractures of th femur the good results were attained by gradua extension rather than by immediate reduction. Tha was the great difference between the direct operativ attack and the attack made by other means. H agreed that spiral fracture of the tibia often require operation, especially when there was also shortenin Sometimes a spiral fracture, with one end riding ov the other, looked very bad by X rays, but was no really unsatisfactory, since by rotating the ank good apposition could be obtained. Sometime fracture of the forearm was very difficult to dea with, especially when the radius came in contac with the ulna, but out of thousands of cases he di not remember more than a dozen in which he had ha to operate. Reduction had to be very carefully carrie out. Operation was required for fractures of th scaphoid. Here the main trouble was dorsiflexion and sometimes there was limitation of flexion of th wrist. His first act in these cases was to increase th deformity, putting all the pressure he could on th scaphoid and semilunar to force it back. If, clinically he got an easy movement of dorsiflexion, he con sidered the case would do well. Otherwise he di not hesitate to cut down at once and remove th obstructing bone. That was much better than delayin operation for weeks or months, for then success wa only partial. For fractured patella in a young ma who wanted a freely movable joint he would alway operate by stitching rather than by putting in plate or pegs or wire. He would not do this in the ol and feeble. It was common to see Pott's fractur plated, although, if seen early, it was one of the easie forms of fracture to manipulate. Whatever metho of treatment was adopted, accidents such as ischæmi paralysis might occur, and many cases arose in th law courts because the operator, not having had th possibility in mind, had omitted to warn the patien

Anatomical Reposition.

Prof. HEY GROVES (Bristol) said it was an accepte principle that operative treatment was indicate when conservative or non-operative methods ha failed. It must be considered, however, what const tuted satisfactory anatomical reposition by no operative methods, and what were the cases whic should be operated on without wasting time on oth methods. He thought the advocates of operativ treatment had gone a little too far in stressing th need for complete anatomical reposition. His vie was that if the length of the bone and the alignmen

were correct, slight lateral displacement was of comparatively small importance so long as contact between ends of the bone was secured. Other things being equal, he was convinced that cases treated by non-operative methods showed a more rapid and a firmer union, with a quicker return to function, than did those submitted to operation. After the ordinary plating operations there was a very slow growth of callus, and union of the bone was tardy. Open fracture was to many surgeons a strong lure towards operation, but often this treatment was followed by great delay, if not indeed by disaster.

To decide which were the cases in which conservative methods were only waste of time was largely a matter of experience and observation, but he would say that fractures in the neighbourhood of joints in which the fragments could not be placed in accurate apposition by manipulation came into this class, as did also fractures of the forearm, and particularly of the radius with ulnar deviation of the distal fragment of the radius. He would also place in this category fractures of the olecranon and patella with wide separation, and fractures of the true neck of the femur in young and vigorous persons. Experience showed that it was usually impossible to bring about accurate reposition of bone without suturing the bone at all. The simplest method was the non-operative manipulation of the bones together, impacting them under the guidance of the fluorescent screen. There were cases in which this could not be done because soft tissue was interposed between the bones; and in those, following skeletal traction, open operation should be done, the bones being fitted together after obstructing tissues had been removed.

Treatment of Some Common Fractures.

Mr. H. A. T. FAIRBANK said that the difficulties of the student and the practitioner arose not so much from ignorance of broad principles as in their application. He should be cautious in deciding without assistance. The surgeon should always keep in mind the enormous difference between operating in the first week and after the lapse of (say) six weeks. This was especially important with fractures involving joint surfaces. In these absolute perfection in the anatomical result of operation was essential, and might be unobtainable unless the fracture was quite recent. Fractures of the shaft, on the other hand, could be operated upon satisfactorily almost at any time. The day of election for operation was, he suggested, the fourth.

Referring to some of the commoner fractures, Mr. Fairbank said that almost the only indication for operation in fracture of the shaft of the *humerus* was damage to the musculo-spiral nerve. With an internal or external condylar fracture, if there was displacement to more than a minute degree, operation should be performed. In external condylar fracture, which was by no means rare in children, the fragment might be rotated by more than 90°, a condition often unappreciated. In supracondylar fracture, if the usual displacement was complete and could not be reduced by manipulation, he thought open operation advisable, provided it could be done within a week of the injury. When six weeks or more had elapsed gross displacement was far better left alone. A nerve lesion should be regarded as one factor in favour of open operation; but when displacement was slight or had been already reduced, a nerve lesion, per se, was not an indication for immediate operation. With fractures of the head and neck of the *radius*, "when in doubt operate." If the head was completely loose it should be removed, but if the periosteum was largely intact the deformity should be corrected and the head should not be removed. Most cases of fracture of the shafts of the *radius* and *ulna* should be operated on if there was overlapping. Colles's fractures only required open operation when they were united in bad position and could not be refractured. Separated epiphysis demanded the same treatment, but this was not so imperative for a relatively small degree of tilting. The displacement that really mattered in a Colles or separated epiphysis was backward tilting; it might be disastrous to function. Moderate backward displacement without any tilting was of no functional importance.

In fractures of the neck and shaft of the *femur*, operation was rarely required if treatment was properly carried out. Plating of the shaft of the femur was advisable, without an attempt at conservative measures, when the soft parts below the knee were damaged or when there was a second fracture in the limb. In the lower third—admittedly more difficult to treat—operation was more often advisable, especially with separation of the lower epiphysis with displacement. In fracture of the femoral condyles operation was imperative if the displacement was more than very slight. The tibial tuberosities were extremely difficult to deal with by open operation, and if fair accuracy could be got by manipulation the fracture was best left alone without operation. Fractures of the shafts of the *tibia* and *fibula*, on the other hand, were very favourable for operation. Want of apposition of fragments was in itself sufficient reason for operation, while overlapping of more than ¼ in. in oblique fractures made it imperative in the absence of contra-indications. "In transverse fractures of both bones with complete disengagement of fragments, operate every time," said Mr. Fairbank, "however slight the overlap may be to begin with." Oblique fractures, if requiring operation at all, should be plated; the transverse usually required no internal fixation.

More than any other joint, the ankle needed absolute accuracy. The lower the oblique fracture in the fibula, the more likely the need for operation. In the young active adult comparatively slight displacement would give a considerable percentage of imperfect results unless operated upon. In those of the third degree operation was much more often advisable, and should be resorted to without hesitation, even in patients somewhat past middle life. In cases of all sorts the slightest outward tilt of the astragalus demanded operation if it could not otherwise be corrected. Backward displacement of the foot must, of course, have been entirely overcome.

Organisation of Treatment and Research.

Mr. W. A. COCHRANE (Edinburgh) said that, in the main, he was in agreement with Dr. Scudder's conclusions, but he thought such discussions as this would be futile until a definitely improved organisation was available. In this direction the Committee of the American Medical Association had done much, for they had encouraged the setting up of centres for the treatment of fractures in hospitals, had improved the teaching of students, and had ascertained the end-results with different methods. The problem now being discussed was one which varied with the particular person who had to look after the case. There were certain fractures which should be operated upon, particularly those in or around joints. Another kind which should be operated upon was that typified by fracture of the lateral condyle of the humerus. Many of these cases were not well controlled by X rays. There was apparently good reposition, but by non-operative means one could not bring about good reduction. In many of the more comminuted fractures which passed into joints he thought it would be well to combine the operation with immediate arthrodesis. For fractures of the diaphyses he agreed that non-operative means should be employed almost wholly. But when time had elapsed a selection must be made. In some cases of spiral fracture of the tibia operation was required. Non-operative methods had proved of great value in diaphyseal fracture, but operations had a definite place in articular and juxta-articular fractures. As a rule, there was no need to fear infection.

Mr. P. B. ROTH thought that operation should always be performed if there were displaced fragments which could not be reduced in any other way. And when operation was needed it should be done as soon as possible after the accident; even in fractured patella he would operate on the following day. The

presence of blebs, if they had not broken, was no bar to operation. Always operation should be done for fracture of the spine of the fibula; also in fractured lower end of the fibula when there was dislocation of the foot backwards. If a fracture could not be reduced under the first administration of an anæsthetic he thought it a waste of time to try again in the same way. He had had many fractures sent to him which had been left untouched because they were compound. He submitted that it should be regarded as an aphorism that displaced fragments must be replaced, even if to do so required an open operation.

Mr. McCRAE AITKEN desired to emphasise the point, made by Dr. Scudder, that it was very important to treat bone as a living structure and not as a mere skeletal and terminal framework. This would greatly help a right conception of what happened when treatment was aided by the use of foreign bodies.

Dr. J. B. MENNELL pointed out that the presence of synovial fluid between fragments inhibited the formation of callus; in joint fractures—particularly at the head of the radius and the lower end of the humerus—a good result could be got by means of movements from outside without fear of anything unpleasant happening.

Dr. SCUDDER, in reply, reminded his audience that fractures had been treated for thousands of years in much the same way as they were being treated to-day, and without, in many instances, reference to fundamental principles. He wished to leave the impression that as a result of a very long experience in this matter, and the experience of the last few years in particular, the profession now stood on very solid and dependable ground, so that it could be said that fracture cases were now being taken care of better than years ago, because practice was based upon agreed fundamentals. The keynote of the situation was struck by Mr. Cochrane; individuals must get together and coöperate, sit at a round-table conference, and compare experiences. This process had been greatly neglected in the past, but a good start had now been made, and he hoped such centres of surgery as London, Bristol, and Edinburgh would get to work on it. The experimental work of Mr. Hey Groves had done much to advance knowledge of fractures. For adequate discussion it would be necessary to pool issues and experiences. It was most important to know accurately what were the actual functional results. He contended that at present the trustees of hospitals were not carrying out their trusts properly in the matter of running the machinery which was to take care of the poor.

SECTIONS OF WAR AND OTOLOGY.

DISABILITY FROM MIDDLE-EAR DISEASE.

ON April 13th these Sections met jointly, with Group-Captain H. V. WELLS in the chair, to discuss the Effects of Middle-ear Disease on Efficiency in Civil and Military Life.

Wing-Commander DAVID RANKEN said that the possible complications of middle-ear disease included recurrent earache, difficulty of hearing, otorrhœa, tinnitus, vertigo, and intracranial complications. Recruits having poor auditory acuity were naturally unsatisfactory, and a cold sufficed to impair it further. Often accused of inattention, these subjects complained that they were passed over when promotions were made, whilst a man liable to vertiginous attacks would not be chosen for positions of danger. The bad effect of this disability on general health accounted for frequent charges of malingering. Flying officers liable to unilateral or bilateral Eustachian obstruction might develop, especially when descending from a height, such severe middle-ear and labyrinthine symptoms that they lost control of their machine. In the Services one view was that men with intractable middle-ear disease should be invalided out; another was that, in view of the expenditure already incurred in training them, efforts should be made to bring about a cure.

With regard to the important question whether the aural standard of recruits was to-day too exacting, Wing-Commander Ranken submitted a table showing that, in 1922, 4·6 per cent. of the rejections of recruits for the Royal Air Force were due to aural disease, the corresponding percentages being 9·2 in 1923, 7·7 in 1924, 9·3 in 1925, and 5·4 in 1926. The average for all the years was 7·4 per cent. As a result of his experience in the R.A.F. since its inception, he did not think the present standard too exacting; indeed, in some respects the conditions were not sufficiently strict. Most of the middle-ear trouble had begun before the recruit entered the Service. Eight years ago he had recorded the result of the examination, by aural experts, of nearly 50,000 aviation candidates, only 2·8 per cent. of whom were excluded on account of aural disease.[1] In a peace-time army he thought there was only one way of obtaining aural efficiency—namely, by excluding all who had had chronic aural disease or who had an upper respiratory tract of the type which yielded a large percentage of aural trouble. This had been done in the R.A.F., and now the amount of aural disease in the flying personnel was negligible. Only those medical officers should be employed on recruiting who had had training in the examination of nose, throat and ear.

The question remained whether conditions should be relaxed in the event of another great war. If so, what alteration should be made? The debatable cases would be those with chronic suppurative otitis media, with or without defect of hearing, who were otherwise healthy. Here the decision should rest largely on the presence or absence of symptoms over an immediately preceding lengthy period. The work being done in school clinics, and the increase of aural specialists in hospitals must lessen the sum total of cases of aural disease, and so produce a higher physical standard among the general populace.

Mr. SYDNEY SCOTT quoted figures issued by the Metropolitan Life Insurance Company of New York, to show the serious economic loss due to aural disease in America. Some limited defect of hearing was very common in the community. If hearing was normal, the residual whisper should be heard at a distance of at least 20 ft., with each ear separately. Mr. H. J. Banks-Davis, who had had much experience in testing candidates for the Civil Service, had given him the following brief indications of the basis on which he worked. As a rule, deafness in only one ear need not disqualify, nor should the accidental rupture of one tympanic membrane. When middle-ear disease had been radically cured by a mastoid operation, an ordinary certificate could be considered six months afterwards. Cases having a history of suppurative otitis media could be given a special recommendation for two years if the condition was inactive at the time. Ineligible persons, Mr. Banks-Davis considered, were those with marked deafness in both ears, suppurative otitis media (if active at the time of the examination), or deafness which was probably progressive. Candidates for the post of Officer of Customs and Excise and in the telephone and telegraph services must have normal hearing. It was important that every defect discovered in the ears of an applicant for service in Army or Navy should be carefully recorded, especially in an otherwise eligible man. A large number of men in the war had aural disorder at enlistment, and many had discharging ears for years, yet a large proportion of these were good and efficient soldiers. It was difficult to separate them from those who had sustained actual damage to the ears in the war. People with a certain degree of otosclerosis heard very well in a noise, and some heard particularly well when the flying-machine was in the air. Men having perforation on both sides did successful flying in the war, and they did not suffer from giddiness, however quickly they might dive. Such cases would be excluded when recruiting in peace-time, but this rule might well be relaxed in war-time.

[1] THE LANCET, 1920, i., 800.

Major W. T. HARE showed by a series of tables and graphs that in a time when it was more difficult than ever to attract recruits an increasing number were being rejected at the medical examination, the increase being partly due to aural disease. Therefore the Army medical authorities had seriously to consider whether the present somewhat stringent regulations concerning recruitment of men with aural trouble, but without accompanying deafness, could not be modified. He adduced a number of reasons for a lowering of the present aural standard. Recently the standard had been that no recruit should be accepted who had any of the following defects: deafness, aural discharge, perforation, radical mastoid operation, dermatitis of the meatus, conditions preventing a good examination of the drum after removing the cerumen, and conditions which had been associated with recurrent headache, deafness, tinnitus, or vertigo which could not be accounted for by the state of the upper air passages. A further reason for asking an easing of the standard was that the examination presumed an expert otological knowledge which many examiners did not possess. Of recruits discovered to be suffering from aural disease or its effects, in less than 10 per cent. was aural deficiency suspected, because most of the men were able to hear orders on parade. In nine out of every ten men having aural defect the condition was present on enlistment, but it might arise in the Service as a result of bathing parades, boxing, exposure to gun-fire, and other causes. Only one ear, nose and throat specialist was employed in each Command, and he had more work than he could conveniently cope with. If more men with aural lesions were likely to be accepted in the Services, it was very important that medical officers should have received special aural training, so that they could take their share of the additional work.

Mr. T. B. LAYTON emphasised the vast difference, in such a question as this, between the circumstances of peace-time and those of a great war. He considered that deafness, giddiness, and an aural discharge ought to be adequate reasons for excluding a recruit. In connexion with giddiness, the important point was the danger of malingering, which could be divided into subconscious malingering and deliberate attempts at deception. If a man had complained of giddiness, it was impossible to insist upon his going back to duty. There was a dread lest persons with discharging ears should develop meningitis, but this was a thing which rarely happened. Active chronic suppurative otitis media was very different from the residual form, which was simply evidence that at some time there had been active disease. He did not see why the latter cases should not be accepted; they were no more liable to acute infections and acute mastoid disease than ordinary people. The radical operation or the modified radical should not be done, he thought, on men while in the Service, as there was always liability to a further breakdown. He concluded by laying stress on the great importance of every recruit being aurally examined, and agreed with Major Hare that more otologists were required in the Army.

Mr. T. RITCHIE RODGER spoke of the relationship between suppuration in the middle ear and deafness in the internal ear due to excessive noise. Some text-books stated that middle-ear disease predisposed to occupational deafness, and therefore examiners of recruits in certain branches of the Services were inclined to at once reject any man who had any middle-ear defect, as he was considered to be more vulnerable to the effects of gun-fire. He wished to insist, however, that so far from middle-ear disease conducing to gun-deafness, the opposite was true; most middle ear conditions were a protection against noise-deafness. Injurious sound waves reached the cochlea by way of the tympanum, not by bone conduction; therefore anything which reduced or damped the normal conducting power of the tympanic membrane and the ossicles would lessen the injury to the delicate nerve-endings of the cochlea. The prevention of noise-deafness was to be achieved by the regular blocking of the external auditory canal, as by vaselined wool, jeweller's wax, celluloid, or rubber. This measure should be obligatory.

Surgeon-Commander J. A. MAXWELL spoke of the prevalence of middle-ear disease in the Navy, which was high in comparison with the total invalidism, higher figures being reached only by diseases of stomach and intestines, catarrh, venereal disease, and injuries. In one year, however, there were only three deaths from aural disease in the Navy. Chronic otitis media, which occurred as a recrudescent disease in older men, should be regarded as a cause of invaliding sine die. Nerve deafness was, in his experience, uncommon; when internal nerve deafness was found, it was due to syphilis more often than to gun-fire. Traumatic rupture of the tympanum was rare. He did not consider that the present Army standard for hearing was too exacting. Abnormalities in the nose and throat should be searched for, as conditions on a modern warship imposed a great strain on the recruit; hence there should be a number of expert medical officers at sea. He felt sure that the increased attention to dental conditions would greatly lessen the septic diseases encountered in the ear.

Sir JAMES DUNDAS-GRANT said that a perforation situated centrally or near the anterior part of the membrane, with a mucous discharge rather than one thickly purulent, was comparatively harmless. It was quite otherwise when the perforation was in the postero-superior segment, close to the attic and aditus. The otologist at the front should realise that a man with cholesteatoma, in esse or in posse, was in a more dangerous position than one who had a perforation lower down. Referring to Mr. Rodger's remarks, he said that Moure, of Bordeaux, had shown that men with nasal, naso-pharyngeal, and throat trouble were more liable than others to suffer from concussion-deafness. Everything pointed to the need of routine otological examination, and it was to be hoped that the authorities would recognise it.

Colonel P. H. HENDERSON said that it had been very disappointing, in 1918, to find that out of every nine men of military age only three were really fit; and even with the present voluntary Army the standard of health was apparently not much better. If the numbers required for the Services were not forthcoming, the physical standard for admission must be lowered. It had been shown that from 30 per cent. to 40 per cent of the children attending school suffered from some physical defect. Yet the Expeditionary Force which went to France in the recent war was admittedly the finest which had ever left any country. In 1923, 323 men were invalided out of the Army on account of suppurative middle-ear disease, 128 for "ordinary middle-ear disease." There was not much evidence supporting the idea that aural trouble greatly reduced men's capacity as fighting soldiers. The middle-ear disease which followed influenza was more amenable to treatment than other forms.

Mr. A. R. TWEEDIE said that of the men who formed the successful force at Gaza 15 per cent. had chronic suppurative otitis media. In peace-time he thought that, if possible, every man who had an intranasal, a postnasal, or an aural lesion should be excluded. And he was pleased to hear Mr. Sydney Scott stress the importance of rhinitis.

Mr. LESLIE POWELL, discussing the question of aural disease before the recruit was accepted for service, said it was hard if a man, having been accepted as fit and continued in the Service, was denied his full pension after the war because it was sought to prove that he had had disease from the ear before becoming a recruit.

Dr. J. H. MACDONALD said that the recruiting figures for the Royal Air Force had not varied greatly in the last few years as regards rejections for aural disease. He agreed with Wing-Commander Ranken that there seemed no reason to alter the standard of examination for ears; the number of recruits required could be obtained, and in an emergency the subject could be reconsidered. In that branch of the Services the system of examination was a

centralising one, and it was easy and convenient to get specialist advice when it was needed. He looked forward to a time when preventive medicine will have made unnecessary so much examination of candidates wishing to enter the Services.

The CHAIRMAN, summing up briefly, said the view which had been expressed that most of the aural disease in the Services was present before enlistment coincided with the view held by the Service medical officers. It needed careful consideration.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society on April 5th, Dr. THOMAS FRASER, the President, in the chair, a paper on

Basal Metabolism in Clinical Medicine

was read by Dr. ALEXANDER LYALL. After referring to the earlier work of the physiologists, he proceeded to describe the method commonly used for calculating the basal metabolic rate (B.M.R.) in clinical practice. The data necessary were the height and weight of the patient, the total volume of expired air over a known experimental period, and the respiratory quotient and oxygen-consumption during the time of estimation. Under suitable conditions uniformity of results was achieved by this method. In one mild case of exophthalmic goitre where the estimation had been carried out four times at intervals of a month the oxygen-consumption had been 254, 251, 255, and 258 c.cm. per minute, with the respiratory quotient about 0·82 on each occasion. The experimental error in the method was about plus or minus 8 per cent., but Dr. Lyall believed that the error tended always to be towards the upper side. Thus a B.M.R. of plus 10 per cent. was within normal limits, whereas a B.M.R. of minus 5 per cent. showed a degree of reduction from which diagnostic inferences could be drawn. Dr. Lyall had investigated by this method, once or repeatedly, a series of 45 cases of exophthalmic goitre. The B.M.R. was increased by 15–30 per cent. in 14 cases, by 30–60 per cent. in 22, and by more than 60 per cent. in 9. The highest rates were plus 87 per cent., plus 97 per cent., plus 100 per cent., and plus 105 per cent. Three of these four severe cases had auricular fibrillation, the patient with the highest rate being a typical case of the fulminant type of the disease. Generally speaking, the group of cases, classed as mild by estimation of basal metabolism, were those likely to become good civil lives within a reasonably short period of medical treatment alone. The cases in the group of moderate severity were likely to stand operation well if there was no other contra-indication. The group with B.M.R. above plus 60 per cent. made poor surgical risks. Additional factors which should be taken into account in considering the operative risk were as follows: (1) there should be no organic heart disease; (2) the blood-urea should be below 50 mg. per 100 c.cm.; (3) the patient should have already regained half the previous loss in weight; (4) the blood pressure should not be higher than 140 mm. Hg systolic and 70 mm. diastolic; (5) the patient should have already regained a fair measure of self-control. In nine of the cases in which glucose-tolerance tests had been carried out, the blood-sugar curves showed inability to deal properly with glucose. The condition should not be confused with true diabetes, although three cases of diabetes mellitus occurred in this series. Eleven cases of myxœdema had also been investigated, the B.M.R. varying from minus 3 per cent. to minus 42 per cent., the average reduction being 14 per cent. In four of these cases exophthalmic goitre had previously been present. A series of cases of toxic adenoma of the thyroid and simple adenoma had shown that the B.M.R. was raised in the former group of cases but not in the latter. In the goitre of puberty the B.M.R. was not increased. The estimation had not been found of value in the diagnosis of malignancy of the thyroid gland.

Reviews and Notices of Books.

RECENT ADVANCES IN MEDICINE.

Fourth edition. By G. E. BEAUMONT, M.A., D.M. Oxf., F.R.C.P., D.P.H.; and E. C. DODDS, M.D., Ph.D., B.Sc., M.R.C.P. Lond. London: J. and A. Churchill. 1928. With 48 illustrations. Pp. 426. 12*s.* 6*d.*

SINCE the appearance of the third edition in 1926 several important additions have been made to this invaluable work. One of the chief of these is a section on the diagnosis of spinal cord compression. Although, normally, the fluid of the cisterna and that of the lumbar spine has the same composition and exhibits similar pressure variations, changes in these factors may occur above and below a block. The cisterna is tapped by Ayer's method, and a lumbar puncture is performed simultaneously; if a spinal block is present, withdrawal of fluid by lumbar puncture will not affect the cisternal pressure, nor will gentle compression of the jugular veins raise the lumbar pressure. The stagnation of fluid below an obstruction causes certain chemical changes, known as the "loculation syndrome"; the protein increases from 0·02 per cent. to 3 or 4 per cent., the fluid has a yellowish tinge due to blood pigment from the congested meningeal vessels, and spontaneous clotting occurs owing to the increase of fibrinogen. In addition to this method lipiodol may be injected into the cisterna and the spine photographed under X rays. A splendid picture illustrating a typical block is given.

A section on the parathyroids sketches the history of research into these glands, and describes the work of Collip, in 1925, in his successful search for a potent extract. The chief use of this is to control the tetany which follows thyroparathyroidectomy; the dosage is still uncertain, but it appears that five units per kilogram of body-weight will raise the blood calcium to normal limits in 24 hours, and much less will maintain it at the normal level. The extract is also effective in other conditions involving a decrease in the blood calcium, such as infantile tetany, but in tuberculosis, although it will relieve some of the symptoms, it is of no fundamental value. The excretion of calcium from the bones which follows its administration is accompanied by an excretion of lead in patients suffering from plumbism, and Hunter and Aub have found the extract valuable in the treatment of this condition. They regulated the dosage by the blood calcium, maintaining its level slightly above normal for varying periods. This drug is a very potent one, and only suitable in selected cases and under adequate laboratory control.

The chapter on the heart has been enriched by a description of the action of quinidine, the understanding of which depends upon a grasp of the "circus" movement that manifests itself in auricular flutter and fibrillation, instead of the radial path pursued by the wave of excitation in the normal heart-beat outward from the sino-auricular node. The circus movement depends upon the presence of a gap of excitable muscle between the head and tail of the wave, and to close this gap stops the movement. Quinidine will lengthen the refractory period of the muscle and so tend to stop the wave, but it may also slow the rate of conduction of the impulse and so perpetuate the movement; which effect it will have depends upon the individual patient. It restores normal rhythm in 50 per cent. of cases, but obviously has very definite dangers. A paragraph on the administration of digitalis by cat unit tablets has been included, and the electrocardiogram of acute thyrotoxicosis is compared with that of physiological tachycardia. In addition to these changes nearly every chapter has been revised and brought up to date. The book was first written as a link between clinical and laboratory workers, as an instructor to the aspirant towards higher medical examinations, and as a stand-by to the busy general practitioner. Its virtue is that it records the practical experience

not merely the theoretical learning, of its authors, and its influence in the propagation of modern knowledge has been, and doubtless will continue to be, very large.

SURGERY OF MUSCLES AND TENDONS.

Die Chirurgie. Eine zusammenfassende Darstellung der allgemeinen und der speziellen Chirurgie. Edited by Prof. M. KIRSCHNER, Tübingen, and Prof. O. NORDMANN, Berlin. The 21st Instalment being Vol. II., Part 2, pp. 867–1104, containing the Surgery of Muscles, Tendons, and Fasciæ, by Prof. W. MÜLLER, Marburg (Lahn). With 108 illustrations in the text and 16 coloured plates. Berlin and Vienna: Urban and Schwarzenberg. 1928. M.17. (Not sold separately.)

THIS instalment of a comprehensive work on surgery begins with the surgery of muscles and includes articles on their normal anatomy and physiology, on their repair when injured, and on free transplantation of parts of muscles, to repair defect or to check hæmorrhage. Degenerative and inflammatory changes in muscles and parasitic affections such as trichinosis or echinococcal disease and tumours, may call for surgical interference, but when the author comes to contracture of muscles and traumatic affections we are on more familiar ground. Ischæmic contracture is fully discussed, though the practical treatment of late results is treated inadequately and without illustrations. Wry-neck and its treatment, including Rowlands's method of lengthening the sterno-mastoid, has a section to itself. The greater part of the instalment, however, is devoted to the surgery of tendons, which is described very fully with the aid of illustrations in the text and in coloured plates. Treatment of the results of direct injury to tendons and that of paralysis by means of tendon transplantation are also well set forth. The surgery of fascia as here described mainly consists of the use of that tissue as a means of repairing injuries and defects of other structures and to form sheaths and ligaments. Its use in place of cartilage and synovial membrane in the making of new joints as in arthroplasty is omitted, as that procedure belongs to the section dealing with the surgery of joints.

This fasciculus contains much valuable information, and the diagrammatic illustrations are clear and should be useful guides to those undertaking operations on muscles and tendons. Like most continental works, it pays little attention to British or American research or practice, although so much work has been done in orthopædic surgery of late years by English-speaking surgeons.

STUDIES IN PSYCHOLOGY.

By WILLIAM ELDER, M.D., F.R.S.E., Consulting Physician to Leith Hospital. London: William Heinemann, Ltd. 1927. Pp. 207. 8*s*. 6*d*.

Dr. Elder attempts in this volume to reduce all psychological problems to a physiological basis. He opens with an account of the neurology of the human organism and passes on to consider memory and the affective conative life. Accepting Herrick's interpretation of will as the anticipation of the future environment based upon power of recall, the author finds himself able to hold a modified view of free will. As an orthodox neurologist and a follower of the old associationist psychologies he has very little use for the current doctrines of the unconscious. Consciousness is essential for reasoning, and the attributing of reasoning powers to unconscious promptings and balancing of these promptings as the Freudians do finds in him little response. There follows a useful chapter on sleep, its mechanism and significance. Sleep to the author is an instinct become habit. This is hard to follow in the sense that instincts are themselves hereditary habits called up by requisite environmental patterns. It is merely the conditioning of the sleep by circumstances that may create sleep habits. The rest of the volume is devoted to dreams and the theory of dream symbols. Here the author finds little use in Freud's conception, and is apparently content with the cheese-before-sleep theory of our grandmothers. At the same time he has many pertinent criticisms of the wilder psycho-analysis of our day and his comment is agreeably free of the venom which characterises so much of the so-called scientific attack on Freudism.

Psychology and the Soldier. By F. C. BARTLETT, M.A., Fellow of St. John's College, Cambridge; Reader in Experimental Psychology and Director of the Psychological Laboratory of the University of Cambridge. Cambridge University Press. 1927. Pp. 224. 7*s*. 6*d*.

Mr. Bartlett, who is one of our leading psychologists, tells us in his preface that during the Great War every important belligerent country called upon its psychologists for advice and assistance, and now lectures in psychology form a part of the course of military study at Cambridge. This book is a selection of lectures delivered in connexion with that course. Research has put on a sound footing tests of intelligence, apart from education, and of special abilities, and the author makes clear their underlying principles; he also brings together the results of recent work on training and fatigue. The section on leadership, discipline, and morale offers an excellent example of the practical utility of organised psychological observation, and the classification of sectional leaders in a complicated organisation like an army into three types, *institutional*, *dominant*, and *persuasive*, is not only interesting, but could be read with profit by whoever is concerned with the selection of personnel in any organisation. The section on mental disorders of warfare is weakened by considering these troubles entirely upon the level of consciousness. This may be done by way of simplification or because the author rejects any theory of unconscious processes, though writers on the subject to whom he refers have all found some such theory necessary in discussing their clinical material. The title of the book was determined by circumstances, but it possesses utility and interest outside the military sphere.

LIPPINCOTT'S POCKET FORMULARY.

By GEORGE E. REHBERGER, M.D. London: J. B. Lippincott Company. 15*s*.

THE earlier half of this book is an index of treatment arranged according to disease. The latter half is divided into three parts; the first of these is a summary of the drugs of the United States Pharmacopœia X., the second a summary of those of the National Formulary, fifth edition, and the third gives a number of new and non-official remedies. In all these parts notes are added on solubility, dosage, action, and use. To the English reader the list of proprietary drugs will probably be of most interest. The treatment advised seems generally sound and is certainly compact in form.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXI., No. 2. Pp. 141. 1928.—Hydatid fluid as an anaphylactic antigen, by C. H. Kellaway (Melbourne). By means of the guinea-pig uterus reaction it is shown that many samples of hydatid fluid contain protein belonging to the host. But, in some cases at any rate, another antigen is present which seems to be a protein derived from the parasite.—Cutaneous spirochætosis due to *Treponema cuniculi* in British rabbits, by D. K. Adams, D. F. Cappell, and J. A. W. McCluskie (Glasgow). "Vent disease" occurs in hutch and wild rabbits all over the world; it is not syphilis but it looks something like it, and the causative spirochæte cannot be distinguished microscopically from *T. pallidum*. It is readily cured by blue ointment or novarsenobillon.—A case of nervous cretinism with histological examination of the organs, by E. C. Eaves and M. M. Croll (Sheffield). Detailed accounts of the anatomy and histology of cretins are not abundant. In this case at 14½ years the pyramidal tracts were still not fully myelinated;

for other details see the original.—Hypercholesterolæmic splenomegaly, by S. C. Dyke (Wolverhampton). A woman with splenomegaly, biliary cirrhosis of liver, chronic interstitial pancreatitis, generalised xanthoma, and a record blood chole terol of 1250 mg. per 100 c.c.m. The spleen gave no microchemical tests for lipoids unless it was first heated, but it contained a great excess of cholesterol on chemical analysis.—The practical application of the direct oxidase reaction in bacteriology, by J. Gordon and J. W. McLeod (Leeds). A new and elegant method of distinguishing the gonococcus in mixed plate cultures.—Causes and sequences in nephritis, by J. Gray (Aberdeen). The author believes, and supports his view with various observations and experiments, that the main cause of common non-suppurative nephritis in man is streptococci. The toxin circulating in the blood is concentrated in the glomeruli by the loss of water which occurs there, and in this way it may rise to a poisonous level till it is diluted again by reabsorption of water in the convoluted tubules. Simple poisons experimentally always cause tubular lesions and not the glomerular damage which can be produced with bacterial toxins and is the primary lesion in man.—The purpura-producing substance in pneumococci and the heritable susceptibility of mice, by W. Mair (London). Pneumococci contain a substance which causes purpura in white mice, especially in a selected inbred strain.—Experiments on the relationship of complement fixation to precipitation, by N. E. Goldsworthy (Cambridge). Complement is fixed in the early stages of precipitation of an antigen by its antiserum depending on the size of the particles.—A precipitinogen obtained from cultures of *B. aertrycke* Mutton, by F. C. Happold (Leeds). A preparation of proteid from broth cultures stimulates the production of precipitins and agglutinins when injected into rabbits.—Experimental monocytosis, by L. J. Witts (Cambridge). Infection with *B. monocytogenes* causes an intense large hyaline leucocytosis; dead organisms have relatively little effect. Extracts of lymphatic glands also excite monocytes.—The two products of thyroid activity, by G. S. Williamson, I. H. Pearse, and H. M. Cunnington (London).—The experimental production of metaplasia and hyperplasia in the serosal endothelium, and of hyperplasia in the alveolar epithelium of the lung of the rabbit, by J. S. Young (Leeds). Extensive metaplasia (including stratified squamous epithelium) of the endothelium of the pleural cavity can be produced by the injection of a mixture of Sudan III. bile-salts and olive oil; the surface alveoli of the lung also show hyperplastic changes.—Blood changes occurring during the course of treatment of malignant disease by lead with special reference to punctate basophilia and the platelets, by R. W. Brookfield (Liverpool). Colloidal lead causes anæmia which is generally quickly regenerated; the characteristic punctate basophilia is due to a degenerative change in young red cells.—The ætiology of hepato-lenticular degeneration; experimental liver cirrhosis; poisoning with manganese chloroform phenylhydrazine bile and guanidin, by E. W. and P. E. Hurst (London). No evidence was obtained experimentally of any connexion between liver cirrhosis and degeneration of the lenticular nuclei of the brain as occurs in Wilson's disease.—Further investigations on selective bactericidal action, by E. A. Cooper and J. Mason (Birmingham). Continuation of the authors' work on "chemical" and "physical" disinfectants.—Pellagra-like lesions associated with deficiency of vitamin B_2 in the rat, by G. M. Findlay (London). Diets which lack the heat-stable component of the complex known as vitamin B lead to the development of a condition as much like human pellagra as can be expected in rats.—Tumours of mediastinum and lung, by T. Shennan (Aberdeen). Most are carcinomas of lung.—The immunity index method of testing antigenic values, by A. T. Glenny and H. Waddington (Beckenham). Periodic Schick tests on guinea-pigs may be used in a variety of ways to measure the efficacy of antigen.—Further notes on spontaneous agglutination of bacteria, by P. B. White (London). The agglutination of bacteria by electrolytes in the absence of specific serum and by non-specific serum may be due to a variety of causes.—The precipitation test in hydatid infestation, by N. E. Goldsworthy (Cambridge). In testing human sera for diagnosis respect must be paid to Dean's principle of optimal proportions.—The cultivation of the gonococcus, by A. Marshall (Khartoum). Agar with red corpuscles.—Book reviews.

New Inventions.

A NEW METHOD OF CUTTING LARGE SKIN GRAFTS.

THIS method of cutting large skin grafts of the Thiersch type, which I designed for plastic surgery at the suggestion of Mr. H. D. Gillies, depends on introducing a flat metal plate (Fig. 1) under the skin

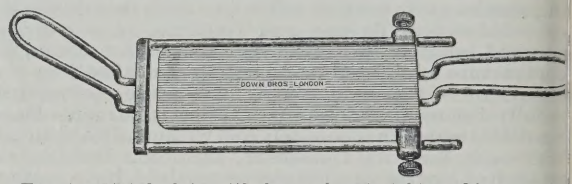

FIG. 1.—Metal plate with frame for stretching skin over it.

and from the flat skin surface produced over the plate shaving off the epithelial layer by a specially constructed knife. The skin and fat is undermined by a large blunt dissector (Fig. 2), the metal plate

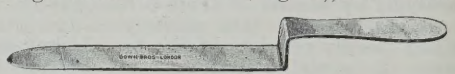

FIG. 2.—Blunt dissector.

being introduced to steady and flatten the skin while it is being stripped of its outer layer. The details of the knife (Figs. 3 and 4), with its attachment to regulate the thickness of the graft cut, are too technical to describe in a short note, but it is sufficient

FIG. 3.—Razor with roller guard.

to say that the knife cannot in any circumstance cut through the skin. The graft is of uniform thickness and its edges are free from serrations. The limits of the mechanism as at present made enable one to

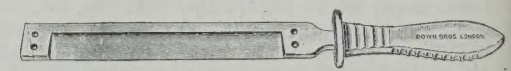

FIG. 4.—Razor with roller removed.

cut grafts from 2 to 4 inches wide by 6 inches in length, depending on the size of plate used; within these limits any predetermined size of graft can be cut with certainty. The only additional wound the patient suffers is a linear incision, through which the plate is introduced under the skin and which is closed on withdrawing the plate.

Briefly the outfit consists of a set of plates of three different widths according to the width of graft desired. Each plate is fitted with an adjustable "fork" which fixes the skin over it, both plate and fork have handles which enable the assistant surgeon to steady it. For each plate, a knife whose cutting edge is 7 inches in length, is fitted with a series of rollers and regulating mechanism, whereby by sawing movement the epithelium is removed.

The device is being made by Messrs. Down Bros, London.

R. LANE JOYNT, M.D., B.Ch. Dub., F.R.C.S. Irel.

THE LANCET.

LONDON: SATURDAY, APRIL 21, 1928.

VOLUNTARY INSURANCE AGAINST SICKNESS.

THE mature student of international social conditions, who looks back to the difficulties that beset his youthful efforts to obtain data on which he could depend, may well congratulate his younger colleagues on the wealth of material so laboriously collected and so admirably presented by the indefatigable workers of Geneva. Information that formerly could be extracted only from a variety of documents, not easy to obtain and certainly not easy to read except by accomplished linguists, is now served up specially prepared for ready assimilation in the publications of the League of Nations and the International Labour Office. In the issue of THE LANCET for March 3rd we had occasion to comment on the monumental study of compulsory sickness insurance issued by the International Labour Office, and the companion volume on voluntary insurance has now been published.[1] Mutual aid among the working classes taking the form of voluntary insurance against disablement through disease or injury is not a new social phenomenon; it can be traced back to the Middle Ages. The craft guilds, to which both masters and workers belonged, made some provision for helping their members in times of disablement, and in the journeymen's guilds, which in the fourteenth century the journeymen, dissatisfied with the craft guilds, began to organise on their own account, this kind of mutual aid was more highly developed. The assistance given took the form of a loan to be repaid when working capacity had been restored. An illustration is found in the following rule of the Fraternity of Bachelor Journeymen of Lucerne in 1560:—

"Every brother who becomes disabled, or falls sick, shall receive the sum of 3½ pfennigs a day if he needs it, but if the Lord restores him to health and enables him to take up his work again, he shall repay the money. If his incapacity is prolonged, and if his needs are greater, money shall be lent to him on security and if he dies the Fraternity shall recoup itself from his estate."

The work begun by the guilds was carried on after their decay and disappearance by other organisations, friendly societies, trade-unions, and employers' welfare schemes; and in the last 50 years it has been much extended and developed; from the Old World it has spread to America, Australia, and South Africa. The proportion of persons voluntarily insured against sickness varies considerably in the different countries, ranging from 1 per cent. in Canada and 1·87 per cent. in Spain to 13·5 per cent. in Great Britain and 14·3 per cent. in Belgium. In Denmark, where there is no compulsory insurance, the proportion of the population voluntarily insured is no less than 57 per cent., but Denmark occupies an exceptional position. The Danes have a genius for voluntary coöperation, and in the field of sickness insurance as in agriculture they have achieved remarkable results without invoking the weapon of compulsion. But the success of the Danish system must to a considerable extent be attributed to the large subsidies from public funds, which amount to about one-third of the total expenditure of the insurance societies. In no other country is assistance given on so generous a scale from public money. In most countries the voluntary insurance societies receive no financial aid from the State, their revenue being derived chiefly from the members' contributions, supplemented by payments, usually on a modest scale, from employers, and by donations, legacies, interest on investments, and receipts from entertainments—in Argentina no less than 35 per cent. of the societies' income is derived from the two last-named sources—but in Belgium, France, Sweden, and Switzerland, as well as in Denmark, valuable subsidies are given to the societies by the central and local public authorities.

It would seem that voluntary sickness insurance tends to develop along the lines followed by compulsory insurance. There is the same tendency towards the organisation of the societies on a territorial basis, the concentration of the membership in a smaller number of societies, and the formation of federations of societies for joint action in negotiating with public authorities, and entering into agreements with doctors and chemists. Similar tendencies may be noted in regard to the benefits given. In voluntary as in compulsory insurance, though with a less rapid development, cash benefits are to an increasing extent becoming relatively less important than the direct provision of medical treatment. Seventy per cent. of the expenditure of the Danish insurance societies is devoted to benefits in kind as against 18·4 per cent. expended in cash benefits. There is a growing feeling that the most important thing to be done for a disabled worker is to restore his capacity to earn wages, and that this end is much more likely to be secured by providing him with the treatment he needs than by the mere payment of money. Treatment benefits have been considerably developed by some societies and include specialist services, institutional treatment, the provision of dentures, artificial limbs, &c. There is also a growing tendency to widen the scope of medical benefits by the inclusion of the dependents of the insured persons. An immense amount of effort is being expended in the promotion of voluntary sickness insurance, but it appears that the prospect for the future is not, on the whole, encouraging. Apart from a few exceptional countries, such as Denmark, voluntary insurance has attracted only a small proportion of the working population. This has been attributed to the natural improvidence of mankind, and also to the insufficiency and precarious nature of the earnings of the low wage workers who are therefore unable to pay regular contributions. But to whatever causes it may be ascribed it seems to be a fact that in most countries a very large proportion of the wage-earners have failed to join provident institutions, and that the failure has been most marked among the poorer workers who stand in the greatest need of assistance in sickness. Moreover, the voluntary societies labour under serious difficulties. Their membership is not constant but tends to diminish considerably in times of economic stress. Their resources, except in the few countries where large public subsidies are given, are limited, and they consequently are at a disadvantage in attempting to make satisfactory arrangements for a good medical service. Their relations with the medical profession in different countries are not always harmonious, and from various parts of the world echoes may still be heard of the "Battle of the Clubs."

Opinion, however, appears to be growing that insurance against sickness cannot be made effective

[1] Voluntary Sickness Insurance: Collection of National Studies. International Labour Office Studies and Reports, Series M (Social Insurance), No. 7. Published in the United Kingdom for the International Labour Office (League of Nations) by P. S. King and Son. 1927. Pp. 470. 8s.

on a large scale without compulsion. This was the decision taken, by a large majority, at the Tenth International Labour Conference in Geneva in June, 1927, and it was confirmed by the International Conference of Unions of Mutual Benefit Societies and Sickness Insurance Funds which was held in Brussels in October, 1927. The decision of the Conference was in the following terms: "The most effective form of systematic provident effort for preventing and remedying the loss of productive power in the workers consists in compulsory insurance, which may be usefully supplemented by voluntary thrift." It would seem that the function of voluntary insurance in the past has been to explore the ground and prepare the way for large national schemes based on the principle of compulsion, and that its function in the future will be to provide means for voluntary thrift supplementing the provision made by compulsory insurance.

PROGNOSIS IN MALIGNANT DISEASE.

THE results of treatment in malignant disease are, on the whole, so unsatisfactory that there is a natural tendency to shirk any attempt at prognosis in individual cases. Every surgeon, of course, can point to instances where his intervention has been completely successful; were it not so, indeed, his task would be intolerable; but he would be the first to acknowledge that his results depend a great deal on factors of which he is ignorant. Of two apparently identical cases, treated in exactly the same way, one may be restored to health, permanently or for a number of years, while the other may terminate fatally in a few months. In attempting to estimate the chances of recovery, the extent of the disease is naturally of the first importance. Involvement of the neighbouring lymph nodes makes the prognosis grave, and further extension makes it practically hopeless. But what is to be said of those cases in which there is no obvious dissemination? It is above all in this group that the position of the surgeon is so difficult. Is he justified in offering the patient the encouragement which is so desirable, or must he still refrain from offering any but the most guarded opinion? Mr. D. H. PATEY and Dr. R. W. SCARFF have attempted to answer the question in reference to that very difficult tumour, carcinoma mammæ, and have brought forward results which are at least encouraging. The number of cases investigated by them is small, being only 50, but, on the other hand, they were all operated on by the same surgeon and were investigated by the same individual, so that variations due to the personal idiosyncrasy of the observer is reduced to a minimum; the period elapsing between the operation and the time of recording the result ranges from three to seven years, which is a reasonably long interval, and the records are complete in every case. In estimating the degree of malignancy of the tumours, they have adopted a histological classification based largely on the work of GREENOUGH, and have relied upon the degree of dedifferentiation of the tumour cells and the apparent rate of growth as evidence of malignancy. After careful consideration of all the available facts the tumours were grouped into three divisions according to the degree of malignancy which they were believed to possess, and were then subjected to analysis in the light of the subsequent clinical histories. It becomes apparent from an examination of the data that the authors were justified in their classification, for their figures show a progressive deterioration in the clinical results as the index of malignancy rises. The duration of the disease before the axillary glands become involved is definitely longest in the group of low histological malignancy, and palliative operations give more prolonged benefit even in advanced cases. It is especially in those cases in which dissemination has occurred, but to a moderate degree, that the value of histology in estimating prognosis is best seen. Of ten such patients belonging to the low and medium malignancy groups, four were alive and well at the time the records were taken, whereas of eight patients in the high malignancy group there were no survivors. It is to be hoped that Mr. PATEY and Dr. SCARFF will continue their work, for it seems to be based on sound lines and to have definite possibilities. The experimental study of cancer has shown that individual tumours differ from one another in their biological characters, their rate of growth, and their behaviour on transplantation. There is no reason to suppose that the spontaneous human carcinomata differ from the experimental tumours in all being built to the same pattern; they also have their individual character which is more rigid and of greater importance than the reaction called forth in the tissues of the host. The amount of stroma and the degree of cellular infiltration are of little value in estimating the growth energy of the tumour. It is the malignant cell itself to which we must look for information, and though it may not be permissible to speak of the correlation of structure to function in the malignant growths it is clear that the structure of a carcinoma has a fairly definite relation to its biological activity.

PUNCTATE BASOPHILIA.

THE nature and significance of the little blue points in red blood corpuscles which stain with the nuclear component of methylene-blue-eosin stains in an ordinary dried blood film have been the subject of a good deal of controversy. Found in small numbers in a variety of abnormal bloods, they have long been known to have a special, though not an invariable, association with lead poisoning, and the whole matter is reviewed in the last number of the *Journal of Pathology and Bacteriology* (1928, vol. xxxi., p. 277) by Dr. R. W. BROOKFIELD, of Liverpool, who has worked at the changes produced in the blood by the administration of colloidal lead in the treatment of malignant disease by Prof. BLAIR BELL. An intravenous dose of lead causes an immediate anæmia by the direct action of the metal on the red corpuscles; to this the bone-marrow responds by regenerating red cells, often very actively, and in consequence the circulating blood shows many immature corpuscles which appear as polychromasic cells in dried films, and as reticulated cells if they are stained wet with a vital stain such as cresyl blue. Punctate basophilic (or stippled) cells appear at the same time, roughly in parallel with the polychromasic cells. Dr. BROOKFIELD produces a variety of evidence to show that stippled cells are in fact polychromasic cells altered by the action of lead. All the stages from typical reticulation to typical stippling can be produced by staining fresh regenerating blood with varying concentrations of cresyl blue, and he quotes the pertinent observation of KEY, who showed that lead poisoning produced less punctate basophilia in normal rabbits than in those whose blood contained many immature red cells as the result of repeated hæmorrhages. It seems, indeed, quite doubtful whether stippled cells occur as such in the circulating blood; several observers have noticed in men and animals poisoned with lead that their number

depended on the precise mode of preparation of the blood films, the quickest fixation giving the least punctate basophilia. These facts are much less easy to reconcile with the view that the stipples are the remnants of a fragmented nucleus, and it certainly seems more probable that they are artefacts due to some action of lead on the red corpuscle, though it is curious that no one has succeeded in producing stippling outside the body by mixing any preparation of lead with normal blood or blood containing many polychromasic cells. The association with lead is so intimate that the discovery of punctate basophilia is an important item in the diagnosis of industrial lead poisioning, and its abundance has come to be regarded as the most significant indication of lead intoxication by the Liverpool Medical Research Organisation. But it is, of course, well known that stippling occurs in pernicious anæmia, malaria, leukæmia, and other anæmias, especially those of a toxic origin, and where the products of red cell destruction are retained in the body; NAEGELI found them in his own blood after an orgy of black pudding. But they occur only when regeneration of red cells is going on, and they are not found in aplastic anæmia, or in states of inhibition or depression of the bone-marrow. Immature red cells are therefore a necessity; these may be altered in a variety of conditions in some way which leads to basophilic points being precipitated inside the cells as the blood film is being made; normally the material remains diffuse and gives the appearance of polychromasia.

Annotations.

"Ne quid nimis."

HOUSING CONDITIONS AND INFECTIOUS DISEASE.

IN order to study the relation between bad environment and infectious disease the Medical Research Council recently made an inquiry into measles in the tenements of Glasgow.[1] Dr. J. L. Halliday, who directed the investigation, points out that school is one of the most important factors in disseminating infection, but that school-children are past the dangerous age. The extent to which they will spread the disease among children under two—who are ten to twenty times as liable to die of it—depends very largely upon home conditions. A special study of certain tenements showed that in these buildings children often became infected at the earlier and more fatal ages, whereas a similar study of a housing scheme area, where each house had its own door of entry, showed that measles was far more usually a disease of school age. Figures from other sources agree with this finding. In Birmingham and Renfrewshire, where the people do not live in tenements, only 45 per cent. of all cases of measles occurred under 5 years of age, compared with 58 per cent. in Glasgow and Aberdeen. The Glasgow figures, moreover, are suspected of being too low. The death-rate under 2 is three times as high in Glasgow as in Birmingham, and the death-rate between 2 and 5 is twice as large. Although Dr. Halliday says that age is only one of many factors, and that the difference in the methods of house construction in Glasgow from those in Birmingham may not be even the main determinant of the difference in the respective death-rates, there is sufficient evidence to prove that the tenement system is deplorably wasteful of child life. There is little privacy; families jostle together in the most intimate manner in the common closes and landings, and the common water-closet is an obvious means of contagion. Children under three are generally carried out to sit on the stairhead, at the close mouth, or in the back court; if they get measles the doctor is not sent for, and the attitude of their relatives is completely fatalistic. An interesting by-product of the research was the demonstration of an immunity among presumably susceptible dwellers in a street almost as soon as a highly infective case appeared. This observation is similar to those made by Dr. de Rudder [2] for diphtheria in Germany. The overwhelming majority of persons in a large town, he says, acquire immunity to diphtheria during the first two decades of life, and the denser the population the earlier is this immunity manifested. He also finds that the effect of crowding is to increase the incidence among the youngest children, and hence the total mortality. This is an important, but not the only evil effect of the tenement system, and the facts cannot be too strongly urged on those who have it in their power to ameliorate housing conditions.

MATERNAL MORTALITY IN CANADA.

A MEDICAL inquiry into maternal mortality was made in Canada during 1925 and 1926, and the results have now been made public in a report [3] published by the Canadian Department of Health. More than 2000 members of the medical profession gave active help in the inquiry, which included records of all deaths of women from 15 to 50 years of age, and the total number of maternal deaths returned was 1532, equivalent to a death-rate of about 6·4 per 1000 living births. It is impossible to assign a specific cause to every death, the contributing conditions mentioned in the returns doubtless overlapping in some cases and being incomplete in others. Puerperal septicæmia was given as causing the death of 418 patients; but since in some provinces the condition is not notifiable, and in others notification is very inadequately carried out, it is probable that this figure should have been higher. Eclampsia and pernicious vomiting were mentioned as causes of death in 242 cases, hæmorrhage in 357, embolus in 87, placenta prævia in 76, nephritis in 80, shock in 63; 136 operations were reported, and 18 letters of advice from physicians expressed the opinion that Cæsarean section was performed too often. Forceps were used in 289 cases. In reply to a question as to the means by which, taking the general circumstances of the patient into account, the physician considered that her life might have been saved, the most frequent answer was "By prenatal care," this occurring 276 times. No prenatal care was given in 1302 cases, and only 12 per cent. of the mothers had anything like effectual supervision before confinement. The term "midwife" in Canada appears to denote an untrained, and usually an incompetent and ignorant woman. The only province in which midwives are licensed by medical authority is Quebec, though Nova Scotia, which permits "any competent female" to practise midwifery elsewhere, makes the curious stipulation that, in order to work in the city of Halifax, she must be trained and certificated. A medical practitioner from Holland reports that the assistance rendered by so-called midwives in Canada, rather than lack of assistance, is often the cause of maternal death, and says that he met with more cases of subacute and chronic puerperal infection in one year in Canada than in 18 years in Holland. Again and again the evidence indicates that lives might have been saved had proper medical care been available; 219 of the women had no medical attendance at birth, and many doctors state that they were not called in until the patient was in labour—sometimes when she was already dying. Generally speaking, maternity has not been treated with the respect it deserves, and letters of advice from the doctors consulted stated that "maternal life has been held in too light esteem."

[3] Maternal Mortality in Canada. Report of an inquiry made by the Department of Health, Division of Child Welfare. By Helen MacMurchy, M.D. Ottawa. 1928.

and that "doctors do not take these cases seriously enough." Other reasons given for the high mortality are poverty, with lack of any domestic help; overwork and resumption of employment too soon after childbirth; inaccessibility, no doctor or hospital being available within distances up to 60 miles or more; and expense, patients complaining that when a doctor charges 65 dollars to visit a normal maternity case at a distance of seven or eight miles, they prefer to take long chances. There can be no doubt that instruction about the value of prenatal care is badly needed by the medical profession, by fathers, mothers, and the general public. The bringing of skilled medical attendance to every mother during pregnancy and at childbirth is a more complicated problem, and almost seems to imply a subsidised medical service in some form or other. This solution has been adopted in Saskatchewan, where a municipal service has been started, but the system is there regarded not as a cure, but only as the best available remedy for the prevailing distress.

SUBLINGUAL ABSORPTION OF MORPHINE.

IT is often convenient to give morphine by the sublingual rather than the subcutaneous route, and in order to test the efficacy of this common practice Dr. David Davis and Dr. David Ayman[1] have conducted tests of absorption. A known amount of morphine sulphate was placed beneath the tongue in the sublingual space, and after a given length of time the contents were washed out and the exact amount of drug unabsorbed was estimated by Gauss's colorimetric method, one-fifth to one-tenth of the saliva collected during each experiment being used. In each case control tests were made with equivalent amounts of normal saliva. The experiments showed that morphine sulphate in the form usually given is not absorbed to any important extent by the sublingual mucous membrane, and Davis and Ayman therefore suggest that administration of the drug by this route should be discontinued. They admit, however, that morphine sulphate is rapidly taken up by the gastro-intestinal mucous membrane, and provided that a patient is able to swallow his saliva, the practical objection to the sublingual route seems to be very slight.

USE OF ALCOHOL IN FEVERS.

AT the recent discussion at the Royal Society of Medicine on the ætiology of alcoholism reported in our columns[2] Dr. J. D. Rolleston stated that he had for many years been convinced that the unnecessary prescription of alcohol in the treatment of fevers, not only in the acute stage but also in convalescence, was not infrequently the causes of converting abstainers into chronic inebriates. Acting on this conviction, as he shows in the current number of the *British Journal of Inebriety*, during the last two years that he has been in charge of a fever hospital, he has reduced the annual consumption of alcohol from 2589 oz. of brandy to 25½ oz. without any injurious effect upon the patients. The mortality from diphtheria in which most of the brandy had previously been used was lower in 1927 when none had been given than in any previous year, though the type of disease had remained the same. He further maintains that the total consumption of 25½ oz. of brandy, most of which was used in the treatment of pneumonia and enteric fever, is considerably less than that used daily at some fever hospitals, where the delusion still lingers that alcohol is a cardiac stimulant or is otherwise indispensable. Dr. Rolleston suggests that the administration of alcohol in spite of evidence of its inefficacy or harmfulness is due to the pressure exercised upon the doctor by the patients' friends, who are under the mistaken impression that in the absence of such treatment everything is not being done that can be to save life or hasten recovery. Although such influence is much more likely to be brought to bear successfully in private practice than in institutions, it is not without its effect even in hospital, and was undoubtedly responsible in Dr. Rolleston's opinion for the administration of some of the 25½ oz. of brandy used at his hospital last year. In addition to the reduction in the use of alcohol in the wards Dr. Rolleston has exercised a strict control over its administration by the ambulance nurses attached to his hospital, who have been ordered to give a report of every case in which they considered such administration necessary, with the amount given. The result of this measure was that during the whole of 1927 only 1 oz. and 7 drachms of brandy were used by these nurses. This figure applies not only to the 3223 patients admitted to the hospital in the course of the year, but to all the other cases removed by the ambulance nurses, amounting to a total of over 12,000 persons conveyed, and a mileage of over 68,000.

SOME RECENT VIEWS ON ANÆMIA AND RICKETS.

THE current theories on the nature of so-called alimentary anæmias of infancy were reviewed last year in an interesting monograph by Dr. H. Baar, of Vienna.[1] The author, who has done much work on the pathogenesis of these disorders, is unwilling to accept Bunge's iron depôt theory as an explanation of the anæmia of premature infants, or of the great majority of others, though he admits the existence of a rare type, "pseudo-chlorosis infantum," which may be due to a pure iron deficiency. The great majority of infantile anæmias are, in his opinion, influenced by dietetic factors and not by iron, and the greater number of these show some signs of dystrophy. The type of alimentary anæmia selected for special investigation was the so-called goat's milk anæmia, commonly attributed specifically to this mode of feeding. His results appear to disprove the idea that there is any essential difference between this type and cow's milk anæmias; the former were as easily cured by giving *larger* amounts of goat's milk as by a change of diet. Czerny's "fat-injury" hypothesis is held to be refuted by Dr. Baar's investigations, which lead him to the view that the great majority of infantile anæmias are "alimentary-infective." The first stage is a quantitative undernutrition, usually accompanied by signs of dystrophy, but not of anæmia. Consequent to this stage the resistance to common infections (bronchitis, &c.) is reduced, and as a result of this anæmia ensues. The improvement obtained by treatment did not show itself simultaneously in the blood-picture and the nutritive state; that of the former depended on the eradication of the infective condition.

It happens not uncommonly that the exact relation of a symptomatic manifestation to the disease which underlies it is revealed more fully by its response to treatment than by any more direct mode of investigation. A further example of this is provided by the interesting observations which Prof. E. Wieland has published[2] on the anæmia which occurs so commonly in children suffering from florid rickets, and is regarded by some authorities as an essential rachitic symptom. His experience has led him to give the first place in the treatment of florid rickets to "indirect heliotherapy," the use of irradiated ("jecorised") foodstuffs. In this paper a series of cases are described, some of whom were treated with irradiated whole milk and others with dried preparations. Prof. Wieland, unlike Dr. Baar, is strongly impressed with the value of observing Czerny's warning against the use of large quantities of milk, and of keeping the maximum allowance of milk per day below half a litre, or one-tenth of the body-weight. He found that considerably smaller quantities were required in

summer than in winter. In the cases described the rapidity of improvement, as shown by the disappearance of symptoms and by alteration of the radiogram, was extremely striking, and greatly exceeded that obtained by administration of cod-liver oil. But the fact by which the author was especially impressed was that no improvement took place in the blood count, more particularly in the percentage of hæmoglobin. This observation was all the more surprising from the fact that various authors have claimed improvement in non-rachitic anæmias as the result of ultra-violet irradiation; it might well be expected that if any form of anæmia responded to irradiation it would be that associated with rickets. As soon as a more varied form of diet was introduced and iron was administered a return of the hæmoglobin towards the normal occurred. Prof. Wieland concludes that this type of anæmia, though an almost constant concomitant of florid rickets, is not an integral part of the metabolic disturbance inherent in this disease; it is merely a secondary anæmia comparable to those which occur in association with many constitutional disturbances of childhood. In another communication [3] the same author reviews the whole question of the ætiology and treatment of rickets, laying particular stress on certain aspects of the disease. In his opinion rickets is common in early infancy and may be diagnosed in the second month. The divergence of opinion between Prof. Wieland and some other authorities on this point is dependent on the interpretation of the significance of craniotabes. Prof. Wieland draws a distinction between a congenital condition (Weichschädel) resembling craniotabes and any form of craniotabes developing after birth; *all* the latter are, he holds, truly rachitic, and the term 'physiological craniotabes" is not permissible. He found it to be the rule that by administration of antirachitic foods the occurrence of craniotabes could be averted in children born at full term, but that in premature children, at any rate in those whose birthweight was less than 2000 g., he was not able to avert the development of craniotabes by any form of prophylactic treatment. Consequently he holds the opinion that rickets is an inevitable result of prematurity, though its severity may be greatly reduced by early administration of antirachitic remedies.

In reviewing the present state of our knowledge of the ætiology of rickets Prof. Wieland posits the existence of an endogenous factor, a constitutional predisposition. The exogenous factors are all ultimately referable to lack of vitamin D; in these factors the climatic element is of greater importance than the dietetic. The synthesis of vitamin D occurs as the result of the action of ultra-violet rays on cholesterin. Of the various methods of treatment the use of irradiated milk is perhaps the most universally practicable, while irradiated cholesterin (ergosterol) is the most rapid and effective.

VENEREAL DISEASE CONTROL: AN AMERICAN VIEW.

INTERESTING aspects of the problems and methods of venereal disease control in America are discussed by Dr. John H. Stokes in a recent article.[4] He comments on the European origin of so many important syphilologic discoveries and finds the explanation in the costliness of research in the United States. In Europe, he observes, professional overcrowding and a lower living standard make it possible to secure able workers for a mere pittance; in America, the country of high wages and high standards of living, this is impossible. The American clinician seems to have his whole time occupied by his patients; he has hardly a moment for original effort. Thus to organise an institution for pure research means the collection of a large sum of money. Work upon venereal diseases is particularly costly; the maintenance of laboratories and of animal hospitals on a large scale present a grave financial problem everywhere. Dr. Stokes mentions that, six or seven years ago, he estimated the annual cost of a not particularly pretentious laboratory for this purpose as not less than $30,000; this budget he has reason to think was much below the mark. We think of America as a country where rich men readily endow the pursuit of knowledge; but Dr. Stokes remarks that private wealth cannot readily be interested in an enterprise which bears the stigma of venereal disease, a topic which is socially unacceptable. If the existing foundations make no contribution and if public funds cannot be made available, he looks to the undertakings which make money out of the technical perfection and sale of the products of scientific discovery in the treatment of venereal disease. He is not without hope of the development of a profitable alliance between the concerns which exploit such products and the universities and research laboratories. Dr. Stokes is inclined to criticise American clinical research as too short-sighted. Such research in syphilis, as he observes, takes years, not weeks or months, for consummation, yet records have not always been organised over a long period, nor has the research worker always adhered long enough to a single line of investigation to secure a significant result. This criticism, of course, comes home to other countries besides America, and to a great extent the problems he discusses are familiar here. The greatest weakness in the situation everywhere is what he calls the "inadequate follow-up." Results cannot be properly traced because, according to his estimate, no higher proportion of patients can be kept under observation than from 20 to 40 per cent. "The perfection of follow-up becomes, therefore, one of the critical problems of the syphilis clinic; and social service, through whose aid it is usually done, plus the strong arm of the local public health officials, become two of the most important implements in this field of modern medicine." Dr. Stokes expresses the opinion that the movement for the control of venereal disease was indistinct in England during the war but has made marked progress in the after-years. American effort, on the other hand, he regards as having become particularly effective in the war period but as having subsided later in an atmosphere of reaction and retrenchment. If he would develop his experiences of "the strong arm of local public health officials," he might help us to decide the controversies which have arisen out of the proposals of the cities of Edinburgh and Glasgow.

CHOLEDOCHUS CYST.

Dr. E. S. Judd and Dr. E. I. Greene [1] state that only one example of choledochus cyst was found among 17,381 operations performed on the biliary tract at the Mayo Clinic from 1907 to 1926. The condition is generally held to be congenital. Of the 64 cases on record 52 were in females and 10 in males, while in two the sex was not stated. The average age was 15½ years, but most of the patients did not present themselves until after the symptoms had lasted for from two months to 36 years. The youngest case was in a full-term fœtus reported by Heiliger, and the oldest in a woman of 56, recorded by Reel and Burrell. Usually the symptoms appeared before the age of 10 years, and many of the patients were not more than six months old. The oldest patient was 20 when the first symptoms were noted. In some cases pain was the first symptom, varying in degree from simple flatulence to excruciating colic, requiring morphia for relief. Eating often precipitated an attack. Jaundice, however, was the most constant manifestation in all the cases reported, ranging from a slight yellowish tint to severe icterus. Generally, it was intermittent, but sometimes it was continuous. Acholic stools were the rule in most of the cases observed. The diagnostic sign of chief significance, according to Judd and Greene, is a tumour which

[1] Surgery, Gynecology, and Obstetrics, March, 1928.

may be barely palpable, or fill the entire abdomen from the costal margin to the crest of the ilium. According to the literature the diagnosis of choledochus cyst has been made only once before operation—namely, by Neugebauer in 1924. The commonest diagnosis has been echinococcus cyst, and the condition has also been mistaken for pancreatic cyst, stones in the common duct, mesenteric cyst, retroperitoneal cyst, cyst of the liver, generalised tuberculosis, chronic peritonitis, ovarian cyst, and cholecystitis. The chief diagnostic features are recurrent attacks of jaundice with pain in the region of the liver, and the presence of a palpable cystic tumour in the right upper quadrant in a young individual, especially of the female sex. As regards treatment any operation should be performed which allows the bile from the cyst to enter the upper gastro-intestinal tract. External drainage has been fatal in all but two cases, the principal cause of death being hæmorrhage. A case seen by Judd and Greene was that of a girl aged 13 years, who from infancy had suffered from attacks of vomiting and abdominal pain which became more severe as she grew older, in spite of removal of the appendix at the age of 8 years. Jaundice had been present five years previously, and again one year before admission. The stools were clay-coloured in the last attack. A tender movable mass was found in the epigastrium, a diagnosis of cholecystitis, probably calculous in nature, was made, and an operation was recommended. A cyst of the common duct, 13 cm. in diameter, being found, an opening was made for the bile to escape, and choledochoduodenostomy was performed. Recovery was uneventful, and a year later the patient reported that she was in perfect health.

POST-GRADUATE TEACHING IN FORENSIC MEDICINE

DISSATISFACTION is often felt because medical students and practitioners have little opportunity of gaining a sound knowledge of forensic medicine. The Council of the Royal Institute of Public Health has therefore arranged a post-graduate course in this subject to be held at the Institute during the summer. It will be divided into five sections devoted to the subjects of evidence; forensic medicine and toxicology; practical toxicology and biological tests; medico-legal pathology; and crime and insanity. The lecturers on these subjects will include Mr. Roland Burrows, Recorder of Cambridge; Dr. Edwin Smith, coroner for the north-eastern district of London; Dr. E. Goodwin Rawlinson and Mr. A. W. Stewart, D.Sc., assistant directors of the State Medicine Laboratories of the Institute; Dr. Robert Donaldson, lecturer on pathology at St. George's Hospital; and Dr. Norwood East, Medical Inspector of H.M. Prisons. Special lectures will also be given by Mr. H. D. Roome and Mr. Gervais Rentoul, M.P. The courses, which will extend from the beginning of May to the middle of July, are described in a syllabus which may be had from the Institute, 37, Russell-square, London, W.C. 1, and a fee will be charged to cover expenses. General approval will be forthcoming for the enterprise, which will undoubtedly be of great assistance both to lawyers and to medical men who are concerned with medico-legal problems.

A SIMPLE HOOKWORM LARVICIDE.

A SIMPLE and effective method of killing hookworm larvæ is announced from the Research Laboratory of the Department of Sanitation of the Rand Mines, Ltd., Johannesburg.[1] Investigating the spread of hookworm infection among white and coloured miners, Mr. W. O. Fischer, Superintendent of the Laboratory, found so many larvæ in the floors of all the pits that he felt some speedy and effective action was urgently needed. As he was at the time examining fæces by the salt-flotation method, it occurred to him to investigate the effect of strong brine on the larvæ. He found that a 10 per cent. brine shrivelled them within their sheaths and killed them in half an hour, a 20 per cent. brine in ten minutes. Dry salt, 1 lb. to a square yard, with half a gallon of water poured on later, was also found to be effective but slower in its action than brine. Apart from its cheapness, salt has the great advantage of not harming men or equipment. In the mine galleries Mr. Fischer found infection concentrated about the latrines (groups of latrine buckets, standing on a cemented or hard earth base), around which he found larvæ in the floors and walls. Dry kitchen salt was spread on two successive days where the buckets stood and on the floor around; seats and floor were sprayed and washed with 20 per cent. brine, the whole proceeding costing no more than 2*s*. for salt. Tested again after four days the floor and walls were found free of larvæ. To make doubly sure Mr. Fischer now puts an inch of salt at the bottom and another inch at the top of each newly provided bucket before it is taken to the destructor; in these he has never been able to find living larvæ after eight hours. The method is so promising that he is now encouraged to hope he may soon see the mines free from infection. Full details of the experiments are given in the paper, and all who have to deal with hookworm in the tropics would be well advised to give a trial to this simple method of protection.

[1] Archiv für Schiffs- u. Tropen-Hygiene, April, 1928.

AURAL DISEASE AND MILITARY SERVICE.

THAT there is a large amount of aural disease among the general population is a fact once more brought into prominence by the discussion at a combined meeting of the Sections of War and Otology of the Royal Society of Medicine last week (see p. 812). It is to be hoped, and it may be expected with some confidence, that the prophecy of Wing-Commander David Ranken may prove a true one, that the work now being done in school clinics, and the increase in the number of aural specialists in our hospitals, will lessen the sum total of these cases. At the present time, however, aural disease is a serious cause of economic loss to the community; this becomes especially apparent in any large organisation such as the Army, and it is therefore natural that the discussion should have been almost entirely limited to the problem as it affects the Services. Two difficulties in particular arise in connexion with disorders of the ear in military life; the first, alluded to by Mr. T. B. Layton, is that of malingering, for if a soldier with chronic aural suppuration complains of pain around the ear, or of giddiness, it is extremely hard to be sure that he is not suffering from some serious complication, and impossible to insist on his return to duty. The second difficulty, which was touched on by Mr. Sydney Scott, is that of distinguishing those cases which have sustained actual damage to the ears during their term of service from those in which aural disease was already present at enlistment. After the late war there were a great many ex-soldiers in this latter class, and many of them had suffered for years from suppurating ears; but where there was no record of the condition on enlistment, it was often impossible to separate the two classes, with the result that many men received compensation for war injury to which they were not properly entitled. Though there is some difference of opinion about what diseases of the ear should exclude candidates for enlistment, it is indisputable that the ears of every applicant should be examined, and that any defect discovered should be carefully recorded. This would eventually prove, especially in war, to be an economy rather than an expense, but it implies that all medical officers employed on recruiting should have had training in the examination of the nose, throat, and ear, and that there should be enough specialists to whom doubtful and difficult cases can be referred. The regulations for exclusion may well be more stringent in peace-time than in war, and naturally

more so for flying men than for others, on account of the danger of vertigo, and the liability to trouble from sudden changes of atmospheric pressure. On the other hand, Mr. Scott pointed out that men with bilateral perforation of the drum-membranes did successful flying in the war, and were in the fortunate position of not suffering from giddiness when diving rapidly, and Mr. A. R. Tweedie stated that 15 per cent. of the successful force at Gaza had chronic suppurative otitis media. The truth is that there are many different types of suppurative otitis, and that some are more dangerous than others. All medical officers examining recruits should be able to recognise a perforated drum, and should be in a position to refer the applicants to a specialist for final decision.

THE King has appointed Dr. John James Rickard Macleod to be Regius Professor of Physiology in the University of Aberdeen in succession to Prof. J. A. MacWilliam. Prof. Macleod, who is a graduate of Aberdeen, has since 1918 been professor of physiology in the University of Toronto. The part which he played in discovering insulin was recognised in 1923 by the conferment of the Nobel Prize for Medicine upon him in conjunction with Dr. F. G. Banting.

THE Founder's Medal of the Asiatic Society of Bengal has been awarded to Sir Malcolm Watson, in recognition of his anti-malarial work in Malaya.

THE next social evening of the Royal Society of Medicine will be held at 1, Wimpole-street, W., on Monday, May 7th. Sir James Berry (the President) and Lady Berry will receive the guests at 8.30 P.M., and at 9.15 Mr. P. B. Tustin will give an illustrated address entitled Milk—from Cow to Consumer.

Summer Time will commence in Great Britain, Ireland, the Channel Isles, and the Isle of Man, next Sunday morning, April 22nd, at 2 A.M., when the hands of timepieces should be advanced one hour. It will end on Sunday, Oct. 7th.

WE greatly regret that a note appeared in THE LANCET of last week announcing, on erroneous information, the death of Dr. I. A. Davidson of Belfast. Dr. T. A. Davidson, of the same city, who died on March 28th, was his cousin.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. E. O'Reilly to *Victory*, for R.M. Infirmary, Portsmouth, and E. S. Bolton to *Constance*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. A. E. B. Wood, Reg. Army Res. of Off., to be Maj. whilst re-employed, and relinquishes the rank of Lt.-Col.

Maj. E. C. Stoney is re-employed.

ROYAL AIR FORCE.

Flying Officer P. H. Perkins is granted a permanent commission in this rank.

INDIAN MEDICAL SERVICE.

Capt. Abani Mohan Ghosh to be Maj.

Lt.-Col. J. A. Shorten retires.

Lt. Shanker Parashram Joshi to be Capt.

Temp. Capt. Samuel Mufty and Temp. Lt. Satya Raju Chittoory resign their temp. commissions.

ARMY DENTAL CORPS.

Seven commissions in the Army Dental Corps will be offered next month. Candidates must be unmarried, under 28 years of age, and must hold the degree or licence in dental surgery of a British University or recognised licensing body, and be registered under the Dentists Acts. Intending candidates should make application, not later than May 7th, to the Under-Secretary of State (A.M.D. 1), the War Office, Whitehall, London, S.W. 1.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXII.—THE TREATMENT OF CANCERS OF THE SKIN.

IT is essential before considering the treatment of cancers of the skin to have a clear conception of the varieties of skin carcinomata, and to be able to recognise them at an early stage. On neither of these important points is much assistance to be had from text-books.

In this country cancers of the skin are usually divided into two main groups: (1) squamous carcinoma; (2) basal carcinoma. The former arising from the prickle cells of the epidermis is spoken of as an epithelioma. When well established it grows rapidly, involves the neighbouring lymphatic glands, and produces metastases in the internal organs. It is rightly considered as being "generally malignant." Whilst the latter, arising from the basal cells of the epidermis, is termed a rodent ulcer because sooner or later it usually undergoes ulceration and if untreated may involve the deeper structures without however invading the lymphatic glands or producing metastases. Hence this, the commoner form, is regarded as being "locally malignant."

Squamous Carcinoma.

The first evidence of an epithelioma is a local infiltration of the skin with central thickening or keratosis. This can be observed when the tumour is no larger than a pin's head, and at first glance suggests nothing more than a plugged follicle. If, however, we excise it and examine it at this stage, we find that the apparent plugging is due to an increase of the keratin layer. A slightly older growth, of two to three weeks' duration, gives a tumour of the size of a small pea, raised above the surface of the skin, of the colour of the skin, with a rose-tinted base due to dilated venules and presenting in its centre hyperkeratosis. If the skin is put on the stretch the periphery of the tumour may appear translucent. The growth is firm, though not necessarily indurated, can be felt to be invading the true skin, and is freely movable in the skin; the tumour has not been invaded by pus cocci; there are no signs of inflammation around it and its contents cannot be extruded by ordinary pressure. The neighbouring lymphatic glands are not involved, and at this stage the epithelioma is quite benign.

Differential Diagnosis.

From what have we to differentiate it in arriving at our diagnosis? Photographically it may simulate: (1) an early basal carcinoma; (2) a small boil; (3) a molluscum contagiosum; (4) a small sebaceous cyst; (5) a mole or (6) a simple wart.

An early non-ulcerated basal carcinoma has a more translucent appearance than a squamous carcinoma. Its centre shows no keratosis, but gives the appearance of a slight depression. The tumour is softer and does not infiltrate the true skin to the same extent. It usually takes two *years* to attain the size of a two *weeks*' epithelioma.

A small boil invariably gives us evidence of inflammation, its necrotic centre exudes pus, and on trying to raise it from the skin it is found that there is infiltration of the dermis for some considerable area around the protuberance. A difficulty arises, however, when the epithelioma has become infected. Such a case was sent to me a short time ago as a rodent ulcer. The lesion was so masked by the super-added infection that though it was easy to exclude rodent ulcer with the history of but three weeks' duration it was not evident that we were not dealing with an infected granuloma. A week's

treatment cleared away the infection and revealed a typical squamous carcinoma.

The tumour of molluscum contagiosum is usually multiple, but even when solitary it can readily be excluded. It is translucent, umbilicated, and soft. Its caseous contents of molluscum "bodies" can easily be expressed. It is more frequently situated *upon* the skin rather than *in* the skin.

A small sebaceous cyst is yellowish-white, translucent, and soft. It does not infiltrate the skin, and, on puncturing, its sebaceous contents can be expressed.

The history, colour, presence of downy hair and softness of the mole should be sufficient to exclude it, whilst the wartiness of its whole surface and the absence of infiltration should rule out the common wart.

Consideration of the above points explains why epitheliomas have, not infrequently, been described as originating in moles, warts, wens, "powkes," cysts, and boils. I have frequently seen cases in which the diagnosis has been missed because due consideration has not been given to their differentiation, and even at times when I have demonstrated what appeared to me to be a typical early epithelioma I have only convinced my audience by subsequently exhibiting a section of the growth. It seems as if it were difficult to realise that such a small innocent-looking tumour is in reality a carcinoma which, if maltreated or untreated, may become highly malignant.

It is not easy to foretell how rapidly the early lesion may progress, nor how soon the lymphatic channels may become invaded, nor yet what character it may assume later, whether superficial or deep, discoid, cauliflower, crateriform, or fungating. It is certain, however, that the less invasion there is of the true skin, the less malignant will the growth be.

Basal Carcinoma.

I have described above the general picture of an early basal carcinoma. The term rodent ulcer is misleading, for a large proportion of these growths are not ulcerated, though they may have been growing for many years. I wish therefore to emphasise the multiformity of basal carcinomas. Clinically, we recognise the following types: (1) superficial-cicatricial; (2) hypertrophic; (3) cystic; (4) morphœiform; (5) pedunculated; (6) nodular and indurated; (7) scirrhous.

When, however, ulceration supervenes and becomes well established, the multiformity is lost in the more uniform picture of the rodent ulcer with its uneven surface, covered by a glairy or hæmorrhagic discharge and its irregular rolled edge, which by gradual erosion may destroy muscle, cartilage, periosteum, and even bone. Fortunately this advanced picture, too often seen 20 years ago, is rarely met with to-day; due no doubt to its earlier recognition and to the more modern methods of treatment.

The *superficial-cicatricial* type is easily the commonest variety; it spreads eccentrically, cicatrizing in parts, leaving scattered nodules within an area (the surface of which often presents a rosaceous tint due to dilated venules) bounded by a well-marked raised gelatinous-looking ridge. The multiple basal carcinomas of the trunk, which are often mistaken for lesions of seborrhœa, psoriasis, lichen planus annularis, or Bowen's precancerous dermatosis, are usually of this variety.

The *cystic* type must be differentiated from sebaceous cysts and lupus vulgaris. The *nodular*—arising from the basal cells of the hair follicles—and the *schirrous*—arising from the basal cells of the sebaceous glands—are not infrequently diagnosed as epitheliomas on account of their induration, but the history of many years' duration should negative this.

Age Incidence.—Multiple Growths.

Though the incidence of cancer is much greater after middle age, one should not let the youth of the patient deter one from making a positive diagnosis. I have frequently seen epitheliomas and rodent ulcers in patients under thirty years of age. Two further points call for mention. If a patient presents a carcinoma on the face, the whole surface of the body should be examined for further growths and the patient kept under observation for years afterwards to note the possible development of further lesions. Multiple growths are far commoner than is usually supposed.

Methods of Attacking the Growth.

Excision.—The treatment of early carcinomas, whether squamous or basal, which I invariably adopt and advise is excision. It can easily be done under a local anæsthetic by the practitioner. It is not necessary to sacrifice more than one-sixth of an inch of the surrounding tissue, nor to dissect out the neighbouring lymph glands, but it is essential to remove the whole thickness of the skin and thus to get *beneath* the growth.

Diathermy.—Epitheliomas of more than six weeks' duration, in the absence of lymphatic invasion, I prefer to remove by means of the diathermy knife. By this method the neighbouring lymphatics and blood-vessels are sealed and the chance of recurrence or of dissemination of the cancer cells is very greatly diminished. If, however, the glands are suspected of being involved block dissection by a surgeon is indicated.

Curetting followed by X Rays.—For basal carcinomas other than the smallest, my method of treatment for the last 25 years has been curetting followed by X rays. The cosmetic result is excellent and "recurrences" very rare. Under a local or general anæsthetic (if necessary) I thoroughly curette the new growth, using adrenalin to stop the oozing, and then apply pure resorcin to the blanched surface, since resorcin has a selective action on epithelial cells. The ulcer is then exposed to a pastille dose of X rays, which is repeated on the two following days. Boric ointment dressing should be applied to the lesion till the ulcer has completely healed, and the patient should be kept under observation for a period of at least two years. So satisfactory has this method proved that I have seldom resorted to other means. Where there is any doubt as to the diagnosis or where it is suspected that the tumour may be a mixed squamo-basal growth, then I would most certainly deprecate curetting and advise excision.

Solid Carbon Dioxide.—The more superficial the basal carcinoma—e.g., those on the trunk—the less readily do they respond to the X rays alone. Hence many workers prefer to use solid carbon dioxide for this type of growth. In the hands of the expert it answers well, but I have had so many rodent ulcers referred to me which have been unsuccessfully treated by solid carbon dioxide that I hesitate to advocate its use. The apparent reason for failure is that it has not been applied long enough nor with sufficient pressure to produce total destruction of the diseased tissue. The cosmetic result is not always satisfactory.

Radium, in the hands of the radium expert, is the most useful method of treatment at any stage of the carcinoma. The resulting scar is supple and usually devoid of telangiectases. Recurrences are few. I have used it for small growths and for recurrent nodules with satisfactory results.

LOUIS SAVATARD, L.S.A.,
Hon. Physician, Manchester and Salford Skin Hospital; Hon. Lecturer, Manchester University.

THE NURSES' CO-OPERATION.—The annual report of this co-operation for the year 1927 shows continued prosperity. The gross receipts from patients amounted to nearly £54,000, of which sum over £50,000 was paid to nurses, while the income of the society derived from commission on fees earned by nurses, together with interest was £3370. The number of nurses on the staff was 38 and 2637 cases were nursed during the year.

FRACTIONAL TEST-MEALS.

ANALYSIS OF RESULTS OBTAINED IN ONE HUNDRED AND SIXTY CONSECUTIVE TESTS.

BY LUCY WILLS, M.B., B.S. LOND.,
CHEMICAL PATHOLOGIST, ROYAL FREE HOSPITAL.

THE work of T. I. Bennett, and J. A. Ryle and others of the Guy's School, has brought Rehfuss's fractional test-meal method into evidence in England, and it is now used in many hospitals as a routine method of examining suspected gastric and duodenal cases. The following paper is a brief report on 160 test-meals and an attempt to evaluate the method as a routine test. I wish to acknowledge my indebtedness to the above authors, whose conclusions largely guided me in reporting on the findings. No attempt has been made to review the literature or describe the methods used.

The cases examined were selected by the clinical staff, and none was omitted from the series save those who vomited during the meal, those (a few only) with very excessive salivation, and those spoilt through some accident (e.g., a case of suspected duodenal ulcer with apparently complete achylia and failure of motility—subsequently found to be taking large doses of belladonna). In all 20 cases were excluded. Acidity is expressed as a percentage of decinormal solution and refers to free acidity (Töpfer's) unless otherwise stated. The following limits have been used to define normality, hyper- and hypochlorhydria, &c.:—

		Per cent.	
Low normal ..	Free acid	10 to 20	0·1 normal NaOH.
Average normal ..	,, ,,	20 to 40	
High normal ..	,, ,,	40 to 50	
Range of normal ..	.. ..	10 to 50	
Achlorhydria ..	No free acid	..	.. Normal chlorides.
Hypochlorhydria	Free acid less than 10		0·1 normal NaOH.
Hyperchlorhydria	,, ,, more than 50		
Achylia	No free acid and very low chlorides.		

Total and mineral chlorides were estimated in a large proportion of the meals, but are not considered in the present discussion except to diagnose achylia from achlorhydria due to excessive neutralisation.

It was assumed for purposes of reporting that the cases examined were suffering from some gastric or duodenal lesion, either organic or functional. Certain findings (some compatible with normality) therefore suggested certain lesions, though the absence of such findings was never held to indicate the absence of a lesion, with the exception of those typical of new growth and pernicious anæmia. These findings can be grouped under three headings: (1) findings suggestive of juxta-pyloric ulceration, (2) findings suggestive of new growth, and (3) findings suggestive of pernicious anæmia.

Findings Suggestive of Juxta-pyloric Ulceration.

A curve of free acidity above 50 per cent. (cases giving single values just above 50 per cent. being excluded) was considered suggestive of juxta-pyloric ulceration, particularly of duodenal ulcer when the rise was rapid, with rapid emptying and continued secretion. No real attempt, however, was made to diagnose ulcers of the duodenum from ulcers occurring at or just on the gastric side of the pylorus. It must be remembered, however, that, without symptoms, such a curve of hyperacidity in no way suggests a lesion, as it is found in 8 per cent. of healthy men and in functional conditions. No attempt was made to diagnose gastric ulcer other than juxta-pyloric by the test-meal findings.

Findings Suggestive of New Growth.

The diagnosis of new growth was made almost entirely on the resting-juice. A foul-smelling, thick resting-juice containing charcoal from overnight, food debris, altered blood, pus, and organic acids was considered absolutely diagnostic. In less marked cases the presence of altered blood in appreciable quantities was considered good grounds for the diagnosis. Some charcoal was nearly always found, however little resting-juice might be obtained. Fresh streaks of blood and swallowed blood (bad teeth and gums) were ignored. The presence of a low or achlorhydric curve was regarded as confirmatory of the diagnosis, but the occurrence of a completely normal curve did not exclude the diagnosis of new growth. The presence of lactic acid (McLean's test) has not been found of diagnostic significance in this test-meal and was not relied upon.

In any case of obstruction food debris, charcoal, and organisms will be found in the resting-juice, but in simple obstruction I rarely found altered blood, except after a recent hæmorrhage. Also in simple obstruction the volume of resting-juice was generally larger and the charcoal not so intimately mixed.

Findings Suggestive of Pernicious Anæmia.

The curve considered typical of pernicious anæmia is one showing complete achlorhydria (low chlorides and rapid emptying). It is said to occur in 4 per cent. of normal people and is frequent in various pathological conditions besides pernicious anæmia. No attempt was made to diagnose other clinical entities, but an indication of the state of the secretory and motor functions was given by a detailed report on the findings.

Test-meal Findings.

In the following review of cases examined the test-meal results are correlated with the operative and the X ray findings, with a view to determining the value of this examination as an aid to diagnosis and treatment, and as an indication for or against certain operative procedures. The actual findings are given here, but the discussion of their value is reserved till later in the paper. The cases are divided for convenience into medical and surgical groups, which are again subdivided according to the operative or clinical findings.

Surgical cases, subdivided according to the lesion found at operation.

1. *Duodenal ulcers.*—Thirty cases occurred in this series, 26 males and 4 females. In 17 of the cases, 16 men and 1 woman, the test-meal findings were such as to have been described above as typical of juxta-pyloric ulceration. In some of these the stomach emptied rapidly ($\frac{3}{4}$ hour) and there was a continuous secretion. In the remaining 13 cases the findings were atypical. The average emptying-time of the whole series was 1·9 hours, the range $\frac{3}{4}$–$2\frac{1}{2}$ hours.

Unfortunately these cases were not all examined radiographically by the same observer. In all 25 cases were examined, and of these 17 were correctly diagnosed and 8 incorrectly. One observer made 10 correct and 1 incorrect diagnoses, but these were selected cases sent from another hospital and so do not represent his real error. There was no relation either in this or any of the other series between correct or incorrect X ray diagnosis and typical or atypical test-meal findings.

2. *Gastric ulcers.*—Twenty-three cases: 17 males, 6 females. These must be divided into those with pyloric or juxta-pyloric ulceration, which should typically show a curve of hyperacidity, and those with ulceration of the body remote from the pylorus, which are not characterised by any definite curve of gastric acidity.

There were 14 cases of juxta-pyloric ulceration; of these 8 had typical findings, 5 had marked obstruction, and 1 gave atypical findings—i.e., the true surgical conditions could be inferred in 13 out of 14 cases. Nine cases had ulceration of the body away from the pylorus; of these 2 gave hyperchlorhydric curves and the remaining 7 normal or low curves. The average emptying-time for cases without marked obstruction was 2 hours, and the range $1\frac{1}{2}$–$2\frac{3}{4}$ hours.

3. *No gastric or duodenal lesion.*—Twenty-eight cases: 14 males, 14 females. The cases in this group, with a single exception which was diagnosed as a case of gall-stones, were clinically considered to have symptoms sufficiently suggestive of a gastric or duodenal lesion to warrant a test-meal examination, but no gastric or duodenal lesion was found at operation. The actual findings were: 7 cholecystitis or cholelithiasis, 7 cases nil found in abdomen, and 1 case ovarian tumour (!). Thirteen cases had their appendices removed, but frequently this organ appeared in no way abnormal!

The test-meal findings in this series were 23 normal or subnormal curves, which, though in no way excluding either gastric or duodenal ulceration, did not suggest juxta-pyloric

ulceration, and 4 hyperchlorhydric curves suggestive of juxta-pyloric ulceration (one of these curves was from a gall-bladder case). One case of gall-stones had a resting-juice typical of a new growth; at operation nothing was found to account for the obstruction, which was apparently reflex in origin; the altered blood in the specimen was not accounted for. The patient has been seen again 18 months later; she is still vomiting and complains of gastric pain; there is a large mass in the pelvis. The average emptying-time for this series was 2 hours, range 1¼–2½.

Twenty-two of the cases had an X ray examination. Twelve showed no gastric or duodenal abnormality, 7 were thought to have pyloric or gastric ulcer, 2 new growth, and 1 a duodenal ulcer.

4. *A single case* will be discussed here, as it is difficult to place it in any class, though it resembles the one reported in some detail in the previous group. The patient, a female, had previously had an operation for apparent pyloric obstruction (symptoms vomiting and pain, X ray delay up to 48 hours). At operation the gall-bladder was removed for stone and a thickened but not obstructed pylorus was noted. X ray a year later showed no delay. Two years later the patient returned with symptoms of obstruction (vomiting, marked loss of weight). On examining the resting-juice, findings typical of obstruction were noted, the presence of altered blood suggesting malignant disease. At operation nothing was found in the stomach and a normal appendix was removed. Eight months later this patient again returned complaining of persistent vomiting. An X ray examination and clinical observation in the ward demonstrated a delay of over 24 hours. At operation adhesions, but a perfectly patent pylorus were found. Finney's operation of gastro-duodenostomy was performed. A post-operative test-meal done 10 days later showed food retention from the day before. This and the previous case are of interest as examples of reflex obstruction, both in cases of gall-stones and both persisting after the removal of the gall-bladder

5. *Malignant disease.*—Fourteen cases: 5 male, 9 female. This small series is of interest as, in my opinion, it constitutes the justification for a test-meal examination in cases with vague gastric symptoms. Two cases in this series had test-meals because the resident medical officer could not think of anything else to do; the diagnosis resulted from this chance, and these two cases were among the four that were operable in the series. The test-meal findings were typical in all cases but one. This case, a man, aged 64, had marked obstruction, but there was a very large volume of highly acid (90 per cent.) resting-juice and no altered blood. The pathologist's report on this case was: "Malignant ulcer of the pylorus of curious type, very localised, and other parts of the stomach very little affected."

The positive diagnosis was correct, therefore, in 13 out of 14 cases. Three cases were wrongly diagnosed as malignant: 2 have been reported in detail; the third case, which had a typical resting-juice and occult blood in the stools though there had been no recent hæmorrhage, was found at operation to have an hour-glass stomach with a large ulcer on the posterior surface, which was adherent to the pancreas. The radiologist had correctly diagnosed the condition, but the surgeon thought, on the history, that the case was probably malignant.

The emptying-time was not determined in many cases, as only the resting-juice was examined, but the average time was 1·84 and the range ¼–2¾. The average in a larger series would probably be higher, as this series included two cases of leather-bottle stomach that emptied very rapidly.

X ray examination was made in 11 cases; in 8 the correct diagnosis was made, in 2 simple obstruction was reported, and in 1 nothing abnormal was discovered; the three latter all had new growth at the pylorus.*

The diagnosis was clear clinically in nearly all the cases, but in 2 cases it rested on the test-meal findings alone.

Post-operative Test-meals.

Sixteen of the gastric and duodenal cases reported above had post-operative test-meals done within a fortnight of their operation.

Six gastric cases.—After partial gastrectomy and gastro-jejunostomy five of these cases had no free acidity and one a free acidity of 18 per cent. (pre-operative value 44 per cent.). Bile regurgitated freely in all and the emptying time was decreased, with the exception of the case mentioned above in which the stomach was not empty at two and a half hours either before or after operation. Only one of these cases had a high acidity before operation, and none emptied rapidly.

Nine duodenal cases had post-operative test-meals. Three had gastro-jejunostomy performed; the result was free regurgitation of bile and reduction of emptying time, but there was free acidity in all three cases, the maximum acidities before and after operation in the three cases being respectively 48 and 20 per cent., 112 and 28 per cent., and 40 and 40 per cent. The case with high acidity before operation emptied rapidly both before and after operation.

Six cases had a Finney's gastro-duodenostomy, and their after-results are of some interest. The change of maximum acidity was respectively 50 to 26 per cent., 90 to 62 per cent., 48 to 54 per cent., 28 to 32 per cent., 62 to 58 per cent., and 70 to 60 per cent.—in no case a marked reduction and in two cases an actual increase of acidity. The emptying time was increased after operation in all cases but one, and in some the delay was very marked. Two patients had appreciable quantities of food debris in their resting-juices after the operation though not before; in neither was the stomach empty when the post-operative meal was ended. Another case, mentioned above, had a large volume of resting-juice containing much food debris, indicating a marked degree of obstruction. Regurgitation of bile occurred in all but two cases. The failure to obtain a marked reduction in acidity and the increase in emptying time noted in all but one case are in marked contrast to the results obtained in gastro-jejunostomies. The fact that there is improvement in symptoms would suggest that acidity is not the major factor in preventing healing.

Non-surgical Cases.

The cases reported below had a test-meal given either because of gastric symptoms or, in the case of anæmias and in certain cases of rheumatoid arthritis, to investigate their gastric functions for therapeutic reasons.

The cases may be divided into two groups—viz., (1) those with either gastric or duodenal symptoms, and (2) those with some general condition.

1. Eighteen cases (4 male and 14 female) had symptoms suggestive either of a duodenal ulcer (2 cases) or of some simple gastric lesion. The test-meal findings can be divided into—normal, 10 cases; achlorhydria, 4 cases; and hyperchlorhydria, 4 cases. The large proportion of achlorhydrias is of interest, especially as all 4 cases were of the achylic type; their symptoms improved on treatment with hydrochloric acid. The average emptying time was 1·7 hours, range ¾ to 2¾ hours.

Thirteen of the cases were X rayed: 8 were reported normal and 5 had either gastric or duodenal ulcer.

The clinical diagnosis was: duodenal ulcer, 2 cases; gastric ulcer, 10 cases; alcoholic cirrhosis, 1 case; gastritis (influenzal, &c.), 2 cases; dyspepsia due to dental caries, 1 case; and gastric neurosis, 2 cases.

Both the duodenal cases had normal test-meal findings, but the case that was X rayed showed a duodenal ulcer. The 4 cases of hyperchlorhydria were all diagnosed gastric ulcer, and the 3 that were X rayed showed a pyloric ulcer. The other 6 cases diagnosed gastric ulcer included the 4 cases of achlorhydria and 2 normal curves. The case of alcoholic cirrhosis gave a low normal curve with excess of mucus, and the X ray was negative.

All improved under treatment and were discharged. Two cases, both women, were examined for the possibility of a new growth of the stomach; both gave normal test-meal and X ray findings. One was probably a new growth of the bile passages; the other was never definitely diagnosed.

2. The non-gastric series consisted of 14 cases of anæmia and allied conditions, 6 cases of rheumatoid arthritis, and 7 cases of general debility.

* Since writing the above I have examined two more cases of new growth, one male and one female. The former had typical findings and at operation an inoperable growth causing marked obstruction was found. The latter case had normal test-meal findings with the exception of pus in the resting-juice; at operation most of the stomach and the first part of the duodenum was removed. The growth was small and localised at the pylorus (no obstruction), and the mucous membrane of the stomach was unaffected, except at one point on the pylorus where the growth was just ulcerating through.

The cases of anæmia can be subdivided into: (*a*) 3 cases, males, of pernicious anæmia; (*b*) 2 girls, children of one of the men in (*a*); (*c*) 2 cases of anæmia of pregnancy of the pernicious type; (*d*) 1 case, female, achylia 20 years ago (Pavlov); and (*e*) 6 cases, 3 males and 3 females, of severe secondary anæmia.

The gastric curves of the individuals in groups (*a*), (*c*), and (*d*) were all similar and of the achylia gastrica type—i.e., no free acid, low chlorides, and rapid emptying (average time 1 hour, range ¾–1¼ hours). The 2 cases in group (*b*) gave curves with no free acid, but the total acidity had maximum values of 15 and 20 per cent. respectively, and both emptied more slowly than the cases in the above groups. The 6 cases of secondary anæmia showed nothing of interest in their test-meals, the range of acidity and emptying time (average 2·1 hours) falling within normal limits. The cases of rheumatoid arthritis, 2 males and 4 females, gave 2 curves of the achylic type, 2 low, and 2 average normal curves. The average emptying time was 1·83 and the range 1–2½ hours. The 7 cases of general debility, 3 male and 4 female, all gave normal curves, with the exception of one, who gave an achlorhydric curve with rapid emptying and a large excess of mucus.

Table I. is drawn up from the cases reported in this paper that had a complete examination, and

rom figures taken from Table V. in Ryle's [1] book. ts moral is the folly of giving percentage values rom such limited series, in which one case will alter he values to such a marked degree.

Summary.

To sum up, the reported findings will be considered from the following points of view: (1) their diagnostic and therapeutic significance; (2) their significance from the point of view of (*a*) the secretory, and (*b*) the motor function of the stomach; (3) sex incidence.

It cannot be too emphatically stated that, with the exception of new growth of the stomach, the test-meal examination gives very little help in diagnosis. In medical conditions such as pernicious anæmia the diagnosis rests upon other examinations. In the surgical conditions other than new growth, a good X ray plate gives far more valuable information. In confirmed cases of gastric and duodenal ulcer the chances are practically equal that the test-meal findings will be the so-called typical ones or normal (or abnormal), so that the fact that the gastric curve is normal will not rule out these conditions. Further, a hyperchlorhydric curve without symptoms in no way suggests a lesion. However, given that the patient under examination has gastric or duodenal symptoms, a curve of the hyperchlorhydric type, if it occurs, is strongly in favour (a 5 to 1 chance) of some juxta-pyloric lesion, though this type of curve may be found (albeit far less frequently) in cases of gall-bladder disease or appendicitis. This is clearly seen in the series of patients in whom no lesion was found surgically, although one was diagnosed clinically. Of these, only 5 out of 28 gave a hyperchlorhydric curve.

It is difficult to sum up the X ray findings, as the examinations were made by different observers. It would appear that a radiologist who specialises in abdominal work can make a positive diagnosis in a large number of cases of duodenal ulcer, though the diagnosis is not so easily made in gastric cases. It would appear therefore that the tendency of certain surgeons to depend more and more on radiographic and test-meal examinations for making their diagnosis is not justified. Undoubtedly a good X ray examination can in many cases decide the diagnosis, but a test-meal examination is only rarely of diagnostic significance. Positive test-meal findings may be helpful, but there are so many gastric and duodenal cases with proved lesions in which the test-meal findings are completely negative that they seem of small value as a routine examination. Further radiographical and chemical work will advance the diagnosis of gastric, duodenal, and other abdominal lesions, but there still appears to be a large field for clinical study.

As a guide to treatment the claims of the test-meal are stronger, as it gives definite information as to the secretory and motor functions of the stomach, which may be disordered apart from any organic lesion. It is argued that a single test-meal can give little information of value as regards the secretory function, as nervous and other influences will render the findings variable; the curve of acidity, however, is not greatly altered in repeated test-meals, but remains of the same type. The findings are of use, therefore, therapeutically, as the beneficial effect of hydrochloric acid medication in achlorhydric cases clearly demonstrates.

The motor function, as judged by the emptying time, is probably more accurately gauged by the fractional test-meal method than is the secretory function. Table II. shows that, except in pernicious anæmia, the variation in emptying time is not related

TABLE II.—*Rate of Emptying of Gruel Meal Relative to (1) Clinical Condition and (2) Type of Curve.*

Clinical condition.	Average emptying-time in hours.	Type of curve.	Average emptying time in hours.

Rheumatoid arthritis	1·8		
Debility	1·8		

to any clinical entity, but is apparently related to the degree of acidity, since the emptying time increases as the average acidity rises. This, according to the findings of J. M. H. Campbell, and J. J. Conybeare,[2] is the reverse of what happens with the heavy barium meal. The determination of the emptying time in relation to secretion is important, because the findings give an indication of the type of operative procedure to be used. In the present series, broadly speaking, three kinds of operation were done for the gastric and duodenal cases—gastro-duodenostomy

gastro-jejunostomy, and gastro-jejunostomy with a partial gastrectomy. The first operation (Finney's) was only done in cases of duodenal ulcer and in one case of spasmodic obstruction; the after-results of this operation are still in dispute, but if the object of the operation is the same as in gastro-jejunostomy—i.e., to decrease gastric acidity by free regurgitation and to increase the rate of emptying—it is not remarkably successful. In no case examined post-operatively was the acidity found markedly decreased, and in several cases it was actually higher. In not a single case was the emptying time decreased. In one case it remained the same and in the others it was actually increased; in fact, in three cases there was still food debris in the stomach after 12 hours' fasting. Gastro-jejunostomy, with or without a partial gastrectomy, was performed on all the remaining gastric and duodenal cases. According to Ryle,[3] in cases with a short history, whose test-meal results show a rapid rise of acidity to a high level and rapid emptying, the operation is contra-indicated, as it frequently fails to produce a lowering of the acidity, and the stomach already empties too rapidly. In the present series all cases, whatever their previous emptying time and acidity curve, showed a marked reduction in acidity after operation. A further examination of their gastric function at a later date would be of interest.

The ratio between the sexes in the cases considered is: duodenal ulcer, 6·5 males to 1 female; gastric ulcer, 2·8 males to 1 female; new growth, 0·6 males to 1 female. Comparing these figures with the death-rate (Registrar-General's figures) from the same diseases, which show respectively a ratio of 4·8 to 1, 1·9 to 1, and 1·2 to 1, there is, with the exception of the small series of new growths, a preponderance of males in this series. This is the more remarkable as in this hospital there is always a large preponderance of female patients.

In conclusion, I should like to thank the members of the staff for permission to report their cases.

SOME EFFECTS OF

ALTERATION OF OXYGEN PRESSURE

IN THE INSPIRED AIR UPON CANCER GROWTH AND BODY-WEIGHT OF RATS AND MICE.

BY J. ARGYLL CAMPBELL, M.D., D.SC. EDIN.,
AND
W. CRAMER, PH.D. BERLIN, D.SC. EDIN., M.R.C.S. ENG.

(*From the National Institute for Medical Research and the Imperial Cancer Research Fund.*)

THE recent researches of Warburg and his collaborators upon the metabolism of tumour cells have shown that these cells can metabolise glucose for a considerable period in the absence of oxygen, and that even their normal metabolism includes both aerobic and anaerobic processes. Warburg [1] also showed that, since cancer cells can derive energy by two different processes of metabolism (respiration and fermentation), it is necessary to interfere with both these processes if one wishes to kill cancer cells by want of energy. He tried to induce this condition by keeping rats bearing implanted tumours for 40 hours in an atmosphere containing the minimum amount of oxygen compatible with the life of the animals (5 volumes per cent. oxygen). As the result of this treatment he found that the bulk of the cells of the implanted tumour were killed. The cells at the periphery of the tumour, however, remained alive and continued the growth of the tumour, so that th treatment did not lead to a "cure." Fischer and hi collaborators [2] used the opposite method, keepin tumour-bearing rats under increased oxygen pressure They based this procedure on the observation that i tissue culture cancer cells can be killed by increasin the oxygen tension. By keeping mice with tumours i practically pure oxygen for 18–24 hours unde 1·6–2 atmospheres of pressure they succeeded i bringing about a disappearance of the tumour in considerable number of animals, but only if th treatment was applied during the first week afte transplantation. Pneumonia frequently occurred i the animals thus treated, and the regression was ofte accompanied by infections of the tumours, with th formation of pus and ulceration. It is well known tha such high pressures of oxygen as those used by Fische are dangerous to man and to most animals, owing t the onset of pneumonia, as demonstrated by Lorrai Smith [3] and recently again by Binger, Faulkner, an Moore.[4] The regression of the tumours is probabl related to infections supervening upon the toxi effects of oxygen on the tumour-bearing animal The suggestion has also been made, although not b Warburg himself, that the genesis of cancer may b the direct result of an inadequate supply of oxyge which would induce potentially-malignant cells t switch over from respiration to fermentation. O that view chronic irritation leads to cancer because i produces a local oxygen deficiency. Auler [5] has recentl applied Fischer's results therapeutically to cance patients by exposing them in pneumatic chambers t increased oxygen tension, and believes that he ha obtained a temporary improvement. In order tha our results might be more directly applied to man we have used oxygen pressures within the limits o safety—that is, increased up to about 60 per cent. o an atmosphere. We have also tested very low oxyge pressures in the inspired air, the lowest average bein 9·6 per cent. of an atmosphere. Normally the oxyge pressure breathed is about 21 per cent. of a atmosphere, so that in our high oxygen pressur experiments we have increased the pressure by abou 200 per cent. above normal and in the low oxyge pressure experiments we have decreased the pressur to a level less than 50 per cent. of the normal. Thi is equivalent to an altitude of about 18,000 ft. B keeping our experiments within these limits we ha the advantage of being able to submit the tumour bearing animals to these different conditions for lon periods of time—2–3 weeks.

Technique.

The animals were exposed to the altered oxygen pressur by enclosing them in air-tight chambers which have bee fully described elsewhere [6]; these chambers were built o the principle recommended by Edie.[7] The animals wer placed in small groups in the usual boxes or cages wit more than sufficient food and water for 3–4 days, so tha the chambers had to be opened only every third or fourt day for renewal of food. This process was carried ou rapidly, so that the total period of breathing normal air a each opening of the chambers was kept below 30 minutes during the rest of the period of the experiment the animal breathed the oxygen at the desired pressure. This pressur was reached by passing through the chambers, as soon a they were closed, the proper mixtures of oxygen and nitroge to give the necessary final oxygen percentages. The oxyge percentage remained remarkably constant without muc further attention, as was shown by daily analysis of the a in the chamber by means of Haldane's apparatus. As th animals used oxygen, carbon dioxide was produced, and thi was absorbed by soda-lime placed in porcelain trays o shelves within the chambers. As the carbon dioxide wa absorbed the pressure in the chamber fell slightly, and fres oxygen bubbled in automatically from a gasometer throug a water-valve. In this way, under ordinary circumstances the whole apparatus could be left to itself for at leas 12 hours without any great change occurring in the oxyge pressure in the chamber. The barometric pressure in th chamber was about the same as that of the outside air— that is, near sea-level pressure—whilst the temperature wa kept nearly constant (about 15° C.) by attention to th heating of the rooms in which the chambers were placed The raising or lowering of the oxygen pressure was performe gradually, and extended over the first four days in eac experiment.

The animals (mice and rats) were fed on a liberal supply of a grain mixture of oats, wheat, and barley with greenstuff and a soft mixture of brown bread and "Quaker" oats, moistened with a little milk. An ample supply of water was placed in the usual receptacles suspended from the top of the cage or box. The cages were kept clean and dry by a thick layer of sawdust, whilst cotton-wool was provided for a nest.

The animals were inoculated with rapidly growing tumours, the rats with Jensen's rat sarcoma and the mice with carcinoma No. 63. Five series of experiments were carried out, each lasting about 14 days. The experiments were controlled by keeping batches of rats and mice inoculated with the same strain of tumours under normal oxygen pressure; in many cases the tumours were weighed and charted in the usual way. In addition controls of uninoculated rats and mice on the same diet and breathing air with normal oxygen pressure were kept.

Effect of Oxygen Pressure upon the Growth of Cancer.

In previous experiments by one of us (J. A. C.) normal animals of various kinds were exposed to air containing abnormally high and abnormally low pressures of oxygen for several weeks. The after-history of the survivors, up to 18 months, has given no indication that either high or low oxygen pressure favoured the origin of cancer; one of the older mice eventually developed mammary cancer, but this occurs in mice which have never been exposed to altered oxygen pressure. In the present research we have exposed inoculated rats and mice to high oxygen pressure, and other similarly inoculated rats and mice to low oxygen pressure. The results for the high oxygen pressure (about 57 per cent. of an atmosphere) are given in Table I., whilst the results for the low oxygen pressure (about 11 per cent. of an atmosphere) are shown in Table II.

r. = rats; m. = mice.

As judged by weights and charts the tumours in the high oxygen experiment grew at about the same rate as the controls for both rats and mice, so that high oxygen pressure does not greatly affect the growth of the very rapidly growing tumours as compared with the controls. On the other hand, tumours of the same strain in the low oxygen pressure experiments (Table II.) showed definitely slower growth than either the tumours under high oxygen pressure (Table I.) or the tumours of the controls. It will be seen that under high oxygen pressure the rat tumours weighed on the average about 8–9 g. and the mouse tumours 1–1·5 g., whilst under low oxygen pressure the tumours in the rats weighed only about 5 g. and those in the mice 0·5–0·9 g. It is of special interest to note that the tumours under low oxygen pressure were much more extensively necrotic, and most of them showed areas of congestion and hæmorrhage. The effect of low oxygen pressure upon the growth of the Jensen rat sarcoma was confirmed by Experiment No. 5 (Table III. and Chart 1) in which glucose was added to the drinking water in one batch of normal and one batch of tumour-bearing rats.

In this experiment the average weight of tumours for two batches of six rats kept under low oxygen pressure was 10·7 and 5·7 g. respectively, whilst the average weight of the control tumours under normal oxygen pressure was 28 g. The inhibitory effect of low oxygen pressure upon the cancer cells is accompanied by a general effect of low oxygen pressure upon the tissues of the body. This is seen clearly by studying

CHART 1.

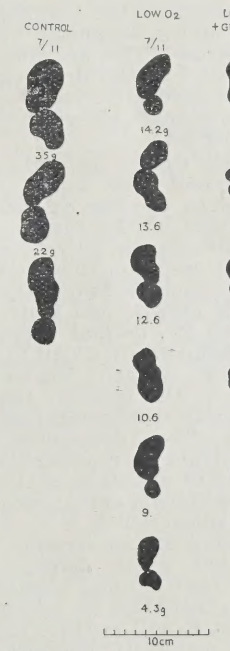

CHART 2.

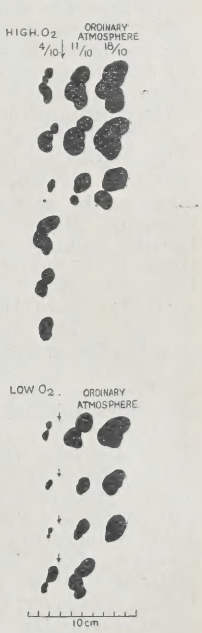

CHART 1 (Expt. 5).—Growth of the Jensen rat sarcoma from Oct. 21st, 1927, to Nov. 7th, 1927, under normal conditions ("control"), under reduced oxygen pressure with and without the addition of glucose to the drinking water. The figures underneath the charted tumours give the weight of each tumour in grammes. The charts illustrate the marked retardation of growth during the exposure to lower oxygen pressure.

CHART 2 (Expt. 3).—Growth of the mouse carcinoma 63 under high and low oxygen pressure from Sept. 20th, 1927, to Oct. 4th, 1927. From Oct. 4th to 18th the animals were kept under normal atmospheric conditions. The chart illustrates the marked retardation of growth under low oxygen pressure as compared with the usual rapid growth during high oxygen pressure. It also shows the resumption of normal rapid growth when the low oxygen pressure was replaced by normal oxygen pressure.

in detail the effects upon weights of the normal body tissues of the animals.

Effect of Oxygen Pressure upon Body-weight in General.

In previous experiments [4] it was shown that normal rats and mice tolerated high oxygen pressure up to 60 per cent. of an atmosphere, and did not appear to be greatly affected as regards body-weight and metabolism. On the other hand, normal rats and mice were adversely affected by prolonged exposure to low oxygen pressure, losing at least 20 per cent. of weight in a few weeks, partly owing to loss of appetite. The low oxygen pressure appeared to affect the heart in particular, and the organs of those animals that died during the experiment showed changes due to marked congestion caused by heart failure. The animals which survived these experiments recovered their good health when they were placed under normal conditions again.

This adverse action of low oxygen pressure was seen in the present research. Under low oxygen pressure (Table II.) the animals lost 18·9 per cent. of their body-weight, whilst in Table III. the loss was about 15 per cent.; these figures are exclusive of the tumour weights. Under high oxygen pressure the animals gained (Table I.) about 13·4 per cent. of body-weight, so that in these experiments the total loss in body-weight due to low oxygen pressure was about 30 per cent. when compared with the high oxygen pressure figures. It must be remembered that the animals were young growing animals, and the increase in weight under high oxygen pressure was simply due to this and not to the high oxygen pressure. The controls under normal oxygen pressure also showed on an average well over 10 per cent. increase of body-weight in two weeks. The animals under low oxygen pressure did not develop any infections.

An attempt was made to counteract the harmful effect of low oxygen pressure in the organism by increasing the consumption of glucose. This was done by dissolving glucose (5 per cent.) in the drinking water. Although this led to a considerable increase in the consumption of fluid by the animals, no evidence was obtained that they were benefited.

The effect on the growth of the tumour as well as that on the tumour-bearing animal lasts only so long as the animals are exposed to the low oxygen tension. In one experiment some of the tumour-bearing animals were allowed to remain alive for three weeks under normal conditions, after they had been subjected to low oxygen tension for two weeks with the usual effect on tumour growth and body-weight. The tumour resumed its normal rapid growth, the animals improving temporarily (Chart 2). In so far as exposure to low oxygen tension produces an extensive necrosis of the tumour, the effect is permanent, but in almost all general conditions studied up to now, as, for instance, dietetic deficiencies, the malignant tissue has exhibited a remarkable independence of the general state of nutrition of the host. Thus, as is well known, a malignant new growth will continue to grow in an organism which is itself dying of inanition. Exposure to low oxygen tensions, however, is a general condition which damages malignant tissue more severely than normal tissue. It has, moreover, this advantage, that since its action extends over the whole organism it will produce its effect on malignant tissue in its metastatic deposits. Unfortunately, it does not damage it so completely as to be of therapeutic value by itself, for since a fraction of the malignant cells survive they resume their growth when normal conditions are re-established.

Summary.

1. Rapidly growing implanted tumours in rats and mice show a greatly diminished rate of growth during prolonged exposure (two weeks) of the animals to low oxygen pressures. This is accompanied by extensive necrosis of the tumours. This confirms the observations of Warburg and his collaborators. Exposure to high pressure of oxygen (60 per cent. of an atmosphere) produces no effect on the tumours.

2. The decrease in rate of growth of the tumour which occurs under low oxygen pressure is accompanied by a decrease in growth of normal body tissues.

3. So far as the experiments go there is no evidence that alterations—within the limits of safety—of oxygen pressure in the inspired air are by themselves of therapeutic value.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Glasgow V.D. Bill.

LAST week the Glasgow Corporation followed the example of the Edinburgh Corporation in adopting by a large majority the draft of a Bill to make further provision for the prevention, notification, and treatment of venereal disease. The Bill represents the end-result of seven years' hard work during which conferences have been held with the sanitary authorities of all the Tyneside burghs and the neighbouring counties. Dr. James Dunlop, Convener of the Subcommittee on the Treatment of Venereal Disease, informed the Corporation that there were 100,000 persons infected with venereal disease within the limits of the city, of whom 75 per cent. were innocent sufferers. Whereas, he said, in contradistinction to tuberculosis, cure could be guaranteed to the persistent patient, it was a fact that one-half of the male patients discontinued attendance before they were free from the risk of conveying infection. The Bill places upon any person who has contracted venereal disease the responsibility for continuing treatment so long as the disease is deemed to be in an infective condition. Should a patient discontinue treatment, the medical practitioner becomes responsible for notifying the case to the medical officer of health, who then requests the affected person to resume treatment. Should he fail to comply he becomes liable to prosecution or removal to hospital on a magistrate's order. The medical officer of health may also require any person who he has reason to believe is suffering from venereal disease, and not under treatment for it, to submit to treatment or produce medical evidence that he/she is not so suffering. In dealing with newly born children suffering from ophthalmia or older children with congenital syphilis, the practitioner must inform the parents, should he have reason to believe that either of them is suffering from venereal disease, but may withhold disclosure of the fact if he is satisfied that the parents' state of health justifies his abstention. The Bill was opposed at the Council meeting by Bailie Miss Snodgrass, who stated that the voluntary principle was having good effect, and that to depart from it and introduce an element of compulsion would prevent people from submitting voluntarily to treatment, and thus lead to concealment of disease. But the amendment which she proposed to refer the draft Bill back to the Committee was supported by only two other members of the Council. Dr. Robert Forgan stated in the course of the discussion that 115 out of 123 doctors in the West of Scotland whom he had approached were in favour of further powers being granted. Progress with the Bill will now depend on the fate of the Edinburgh Bill.

THE ROYAL COLLEGE OF SURGEONS AND CANADA.

THE QUESTION OF AN IMPERIAL DIPLOMA.

SOME two years ago the Canadian Medical Association, which is anxious to improve the standard of medical education in the Dominion, invited the Royal College of Surgeons of England to consider whether means could not be found to make it easier for Canadian graduates to attain the Fellowship of the College. It was pointed out that expenditure of time and money on a journey to London was often prohibitive, and it was suggested that examinations should be held in Canada. Last May the Council of the College decided that "it is desirable to send examiners to the Dominions to conduct a Primary Examination for the Fellowship, of the same standard as the examination in this country . . . provided that satisfactory arrangements can be made." After negotiation with the Canadian Medical Association a scheme has been approved whose provisions are as follows :—

1. The Canadian Medical Association to be appointed the authority in Canada representing the Royal College of Surgeons in connexion with the proposed examination, and to be responsible for the arrangements to be made in Canada to enable the Examiners of the College to conduct the examination in that country.

2. An examination to be held by the College at Toronto at the end of July or in August, 1929, provided that it is notified to the Secretary of the College not later than May 1st, 1929, that there are such a number of eligible candidates desirous of being examined as may be agreed by the College and the Canadian Medical Association as sufficient to warrant the holding of an examination in Canada.

3. Two Examiners in anatomy and two in physiology, who shall be present or past members of the Board of Examiners in Anatomy and Physiology for the Fellowship, to be sent by the College from England.

4. A professor of anatomy and a professor of physiology, or such other persons as may be nominated, to be appointed by the College from names submitted by the Canadian Medical Association to act as assessors to the Examiners.

5. The examination, written and viva voce, of each candidate in each subject to be conducted by two English Examiners and one Canadian assessor.

6. The Canadian Medical Association to be invited to appoint suitable persons to visit and inspect the examination.

7. The questions for the written paper in Canada to be set by the Board of Examiners in Anatomy and Physiology for the Fellowship at the same time as those for the written paper for the June examinations in England, and to be taken to Canada by the Examiners sent from England.

8. The written paper examination to be held on the arrival of the Examiners in Canada, and the viva voce examination as soon after as convenient.

9. The result of the examination to be determined and announced by the Examiners in Canada on the completion of the examination.

10. Notice of the date and place of the examination to be given in the *Journal of the Canadian Medical Association* and in such other way as may be thought desirable.

General satisfaction will be felt at the forging of this link between surgical practice in England and the Dominion of Canada. If extended to other parts of the British Empire, the arrangements would help to establish the Fellowship as an Imperial diploma for post-graduates, and would raise the general standard of practice. The alternative is for each of the States of the Empire to set up its own standards and institutions without reference to the rest—a tendency illustrated by the recent formation of the Surgeons of the College of Australasia. The success of this alternative depends on the wisdom with which new traditions are established and on the enthusiasm with which they are inspired. National institutions have the merit of commanding national interest, and competition between them is undoubtedly healthy; on the other hand, a common organisation does something to promote a valuable community of thought among workers in the same field.

Public Health Services.

THE N.H.I. AMENDING BILL.

DISCUSSION ON SECOND READING.

(FROM AN OCCASIONAL CORRESPONDENT.)

YOU were well advised in giving so large a space in your last issue to the debate on the National Health Insurance Bill, for the second reading of any Bill in the House of Commons is generally used as the means of informing the public what are the principles involved in the Bill. And the public are in dire need of enlightenment on the further development of an insurance scheme which has already made so profound a change in medical practice and is likely as time goes on to have still greater an effect in modifying the work of the general practitioner. The scope of the Bill is very limited, but it must not on this account be regarded as unimportant. The primary object of all legislation which alters the administrative machinery of the Insurance Act should be the promotion of the health of the insured person. Provision of adequate treatment in illness, speedy restoration to normal working capacity, and prevention of sickness amongst the workers are all objects well within the scope of the original Act, and there seems to be a serious danger of these objects being overlooked in the consideration of the interests of the various authorities administering the scheme. The Bill, in fact, is disappointing as a step in the development of the insurance scheme, though certain clauses are to be welcomed. It is true that the arrears scheme does mitigate the hardship of the unemployed insured person to a satisfactory degree and materially helps the approved societies in the administration of benefit. The improvement in the condition of the Deposit Contributors' Fund, whereby the benefits obtainable by "bad lives" will approximate more closely to those of the ordinary insured person, is all to the good. An important move is made in Clause 14 (3) which empowers the Minister to make regulations for the administration of additional benefits, and provides against such an inrush of new members to any society offering some attractive scheme as might prejudicially affect its financial position.

The administration and regulation of any additional benefits that may be offered by a society is likely to be a thorny point. In this connexion Clause 14 is strongly opposed by the approved societies. A letter circulated to Members of Parliament by the Association of Approved Societies says "the Bill is also designed to interfere with the self-government of societies by their members and to substitute therefor the bureaucratic fiat of the Department." Neither does this clause find favour with the insurance committees. If any of these additional benefits become statutory they should be administered by insurance committees like general medical benefit, and it is feared that Clause 14 in conjunction with the repeal of Section 75 (5) of the 1924 Act will prejudice the rights of insurance committees in the future. Section 75 (5) of the 1924 Act provides that : "Additional benefits shall be administered by the society or branch of which the persons entitled to benefits are members, except where the benefits are in the nature of medical benefit, they shall be administered by and through the insurance committees." The third schedule of the present Amending Bill repeals the section just quoted "as the Regulations to be made will make provision for the manner in which the several additional benefits are to be administered" (see p. 13 of the explanatory memorandum). It is possible to conjecture from all this how varied and mutually opposed are the claims of the various bodies who take part in the administration of the Act.

The political interests involved probably explain much that has been left out of the Bill. After the passing of the Economy Act in 1926 it was natural to attribute the shortcomings of any legislation or action

of the Ministry to the lack of funds. But in the course of the debate it was definitely stated by the Parliamentary Secretary on behalf of the Ministry that "but for the opposition of the approved societies of the country it would be perfectly possible to put into operation the scheme of the specialist services without bringing any additional funds into the national insurance system at all." The Royal Commission stated that if the approved societies could agree to pool their funds the scheme could be put into immediate operation. It is clear, therefore, that the Government have had considerable difficulty with the vested interests, and this is probably the real explanation of the fact that two of the most important recommendations of the Royal Commission are left out of the Bill—namely, the pooling of surpluses and the abolition of insurance committees. The Economy Act may have had a direct influence, for it was pointed out that the amount available for investment by the societies fell from £8,000,000 in 1925 to £200,000 in 1927, and it was on the interest from these investments that the additional benefits depended. The extension of maternity benefit to cover medical and midwifery services, the extension of the scope of medical benefits to the dependents, and the provision of specialist services and laboratory facilities, all highly desirable, are apparently blocked by the failure of the societies to agree to a unified administration with the pooling of funds. It is interesting that in certain areas—for example, in South Wales—the much criticised medical aid institutions (which could be approved under the Insurance Act) are providing a more extended service; this includes expert advice, special treatment, laboratory facilities, dental and ophthalmic treatment, and professional nursing.

It is time that a long view should be taken of the economics of national health insurance. Any development which increases the facilities for improved diagnosis and prompt and adequate treatment would be an economical move. The experimental dental clinic which is to be set up in certain areas may be an important indication as to future activities.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the 1927 statistics of the County Borough of Reading and Borough of Poole:—

Name of district and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhœa, &c., under 2 years.	Maternal mortality from childbirth.
Reading .. .. (94,660)	15·3	12·3*	0·99	1·27	2·1	1·6	42/25	2·7	2·1
Poole .. .. (51,030)	17·5	12·3*	0·71	1·45	2·4	1·4	58/33	4·5	0·0

* The standardised death-rates of 10·7 for Reading and of 10·3 for Poole may be compared with the rate of 12·3 for England and Wales.

Reading.

Dr. H. J. Milligan reports that the infant mortality is lower than it has ever been before. The improvements to the maternity home have been completed and have greatly added to its efficiency. The extensions to the isolation hospital have also come into use. A joint committee representing the county borough council, the board of guardians, and the Royal Berkshire Hospital have gone into the question of the hospital accommodation of the borough. The principal deficiency found was a lack of beds for acute surgical cases. The Royal Berkshire Hospital propose to establish a branch hospital with immediate accommodation for 60, and capable of expansion to provide for 240. This branch hospital will provide for diseases of bones and joints, which at present occupy beds for long periods, and also open-air treatment for post-operation cases. The joint committee agreed that the present coöperation between the various hospital authorities was quite satisfactory.

Paratyphoid fever was unusually prevalent from May to December. There were 44 notifications and no deaths. No special reason could be assigned for the prevalence except the passing on of infection by mild and "missed" cases. There were also six notifications of true enteric fever of the severe type with two deaths. Towards the latter end of the year a very grave form of diphtheria appeared. There were 74 notifications and 17 deaths, giving a case-fatality of 23 per cent. Between October, 1927, and February, 1928, 64 diphtheria patients were admitted to the isolation hospital, of whom 14 died. Of those who recovered, 16 suffered a long illness with complications such as marked toxæmia and paralysis. Of the patients who died the disease had usually reached the fourth or fifth day before admission to hospital, too late for antitoxin to be of any avail. The Borough of Reading Medical Society, Ltd., and the Reading Public Dental Service, Ltd., provide medical and dental treatment for the dependants of insured persons and others whose incomes do not exceed £250 per annum. At the Tuberculosis Dispensary, out of 73 contacts examined, one was found to be suffering from non-pulmonary tuberculosis, 19 showed suspicious symptoms, or signs needing continued observation, and 53 showed no clinical signs of infection. At the V.D. Clinic the new cases of syphilis continue to decline. In 1927 there was a sudden drop in the congenital cases, which Dr. Milligan thinks is due to the cases not being sent to the clinic as freely as before, rather than to an actual decline in the cases. In the 1927 returns there is a new heading for 21 patients who left off treatment before being cured and returned after six months or more for further treatment.

A table shows that since 1905 the neonatal mortality has declined from about 35 to 25, the infant mortality from bronchitis and pneumonia from 17 to the neighbourhood of eight, and that from gastro-intestinal diseases from 17 to the neighbourhood of three. Dr. Milligan reports that antenatal supervision is being carried out efficiently by the younger and more highly trained midwives, and that those midwives who are not capable of doing this work themselves, encourage their patients to attend the antenatal clinic. The antenatal clinic was attended by 250 new patients, who made 999 attendances. A record is now made of the blood pressure of all patients attending this clinic.

Of 55 samples of milk examined bacterially four were found to contain living tubercle bacilli. In three of the cases the infected animal was traced and destroyed. The housing committee has had under consideration the question of slum property. During the last seven years 62 slum houses, representing one-fifth of those recommended for demolition, have been demolished. Owing to the house shortage it is not possible to deal with the others, or to find a remedy for overcrowding in most cases. The municipal houses completed numbered 332 and subsidy houses 148, but the level of the years of moderate building activity before the war has not yet been attained. The school report especially emphasises the difficulties of the dental scheme owing to a quite inadequate staff.

Poole.

Dr. R. J. Maule Horne reports that a considerable proportion of the 499 new houses have been erected in semi-rural districts, which were unsewered, and that in many cases the road access to these houses is precarious. As a result the number of cesspools which the health department has to empty, has increased from 490 in 1906 to 610 in 1927. An additional 100 cesspools expected in 1928 will increase the difficulties of the cleansing department. A year ago the housing shortage was estimated at 518. A

ıe end of 1927 it was estimated at 309. Dr. Horne ould like to see a model lodging-house erected, pecially for the accommodation of visiting seamen. Energetic efforts are made to cope with rats, both the borough and port, but the refuse tips add to ıe difficulty of dealing with them. At the present me tipping is used for reclaiming land, but Dr. orne hopes that the reclamation scheme will soon e complete and a more sanitary method of refuse sposal adopted. Spraying with paraffin is adopted r the fresh-water lakes and ponds in order to ep down the mosquitoes, and attention is given to eping the water courses clear and avoiding sluggish -pools. Dr. Horne presses for a public abattoir. considerable proportion of the butcher meat nsumed in Bournemouth is killed and dressed in e Poole slaughter-houses, which number 12, and e scattered over an area of some 12 square miles, us rendering inspection very difficult. Late in e year the Southern Sea Fisheries' district committee issued licences for the dredging and relaying 50,000 oysters. There are now some 200,000 rsons living close to the shores of the harbour and consequence the oysters have to be relaid at ipstal, in the Arne reach of the harbour. The se season extends from May 15th to Sept. 30th. A table for the years 1907 to 1927 shows that ere has been during that period an even greater duction in the child-mortality from one to five years an in the infant mortality-rate. Thus, in the rlier years of that period the one to five years ild deaths were over 40, whilst during the last ır years they have been 21, 20, 11, and 9 respectely. The infant deaths, on the other hand, ring the earlier years were in the neighbourhood 80, and during the last five years they have varied m 46 to 60.

FECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 7TH, 1928.

Notifications.—The following cases of infectious ease were notified during the week :—Small-pox, 3 (last week, 322) ; scarlet fever, 1622 ; diphtheria, 30 ; enteric fever, 32 ; pneumonia, 1345 ; puerperal er, 52 ; puerperal pyrexia, 103 ; cerebro-spinal er, 6 ; acute poliomyelitis, 7 ; acute polioephalitis, 1 ; encephalitis lethargica, 29 ; contued fever, 2 ; dysentery, 23 ; ophthalmia natorum, 99. No case of cholera, plague, or phus fever was notified during the week.

The cases of small-pox were notified from the following counties : London, 1 ; Bedford, 7 ; Chester, 2 ; Derby, 6 Durham, 92 ; Gloucester, 2 ; Kent, 1 ; Lancaster, 35 ; coln, Parts of Lindsey, 1 ; Middlesex, 1 ; Norfolk, 1 ; thumberland, 13 ; Nottingham, 2 ; Stafford, 3 ; rey, 1 ; Warwick, 7 ; Yorks, North Riding, 3, West ing, 69 ; Glamorgan, 38 ; Monmouth, 33.

The number of patients in the Infectious Hospitals of the ropolitan Asylums Board on April 10th–11th was as ows : Small-pox, 7 under treatment, 4 under observa- ; scarlet fever, 1601 ; diphtheria, 2368 ; enteric r, 31 ; measles, 1542 ; whooping-cough, 136 ; puerperal r, 16 (plus 15 babies) ; encephalitis lethargica, 66 ; er diseases, 31. At St. Margaret's Hospital there were ases of marasmus, and 14 babies (plus 6 mothers) with thalmia neonatorum.

Deaths.—In the aggregate of great towns, including ndon, there was no death from small-pox, 3 (2) from eric fever, 144 (82) from measles, 5 (1) from scarlet r, 41 (6) from whooping-cough, 44 (13) from htheria, 34 (8) from diarrhœa and enteritis under years, and 108 (6) from influenza. The figures arentheses are those for London itself.

f the 62 fatal cases of measles outside London, 7 were rted from Willesden, 5 from Sheffield, 4 each from t Ham and Salford, and 3 each from Brentford and wick, Plymouth, and Manchester, while the figures in burgh, Glasgow, and Dublin for the same week were , and 9. Of the 35 fatal cases of whooping-cough, ch were reported from Birmingham and Liverpool, and m Newport (Mon.).

number of stillbirths registered during the week 258 in the great towns, including 46 in London.

Correspondence.

"Audi alteram partem."

HAS THE CAMPAIGN AGAINST VENEREAL DISEASES BEEN A FAILURE?

To the Editor of THE LANCET.

SIR,—The statement in your last issue (page 773) that medical authorities in Edinburgh, after an exhaustive trial, are convinced that the "voluntary system cannot control or eradicate venereal disease in a reasonable time . . . and they are of the opinion that it must be reinforced by compulsion," has raised, in an acute form, the fear that has been worrying us in England for some time, that all is not well with the scheme promulgated by the Ministry of Health in 1917. Venereal disease is not diminishing in England. During the last three years, for which figures are available (1924–26) syphilis has remained stationary around 22,000 per annum, and gonorrhœa increased from 30,000 to 35,000. If this increase meant that more cases attended the clinics, because they knew of the facilities for treatment, it would be a matter for congratulation. But apparently, in Edinburgh, they do not think so, and in this I am inclined to agree.[1] Instead, they stress the point that of the annual 3000 who attend their clinics, about 33 per cent. default before cure ; and to this they attribute the persistency with which the numbers keep up. It is to deal with these defaulters, and the other cases which never come to any qualified source for treatment, that they wish to obtain compulsory powers.

It may be interesting, then, to compare the figures in Edinburgh with those in London for the same period, and see what we can deduce from them. In 1921 the total attendances in London were 19,368. In 1926 they had dropped by 8 per cent. to 17,724.[2] Analysing these figures one finds that the diminution is entirely due to the fact that syphilis dropped from 8188 to 5738, whereas gonorrhœa rose from 10,709 to 11,683. Here, I think, we can put our finger on the weakness inherent in the scheme originated by the Ministry of Health. That weakness is that the conditions governing the successful treatment of syphilis and gonorrhœa are radically different.

Syphilis is a disease that readily lends itself to out-patient treatment. With the powerful arsenicals now at our disposal we are able, temporarily, to render patients non-contagious from the public health standpoint with extreme ease and rapidity. This is what the Ministry aimed at ; for it was not out, primarily, to cure syphilis, but to treat it in the "early and communicable" stage—in other words, to render it non-contagious. In practice, of course, it is not desirable to stop at this stage. The clinics have not done so, nor have the Ministry objected in any way, though this prolongation of treatment is not inherent in the scheme, which is essentially drawn up from the view-point of the public and not the individual. Luckily, even with this extended view, a weekly or bi-weekly attendance at a venereal clinic is amply sufficient for the vast majority of cases of syphilis.

In the cure of gonorrhœa, however, we are not in anything like as happy a position. Here out-patient treatment is but a poor substitute for in-patient care, even in males, as everyone with knowledge of the work in the Services will agree. Treatment, moreover, is much more complicated in gonorrhœa than in syphilis ; there is a much greater loss of working time owing to the frequent necessity of attendance daily for irrigations, &c. ; and, worst of all, the period of infectivity has not been diminished appreciably in the last 20 years, simply because we have nothing

[1] Edinburgh Corporation Bill, 1928. Venereal Diseases. Statement for the Corporation. Beveridge and Co., 23, Abingdon-street, S.W. 1.

[2] L.C.C. Annual Reports, 1926, Vol. 111.

in our armamentarium against gonorrhœa comparable to arsenic in syphilis. Defaulting, therefore, is much more common, and gleet is still the greatest bugbear we have to contend with. When we come to consider the treatment of gonorrhœa in the female, we find that we are still worse off. Gonorrhœa in the female is a most intractable disease. It has been asserted that it is incurable. This is nonsense; but the fact remains that, as far as out-patient treatment is concerned, cure is exceedingly difficult. From the public health standpoint this is a most unfortunate circumstance, because one woman can infect 100 males in less than a year, and, with the best out-patient treatment, infectivity may last in women for years. Women require, even more than men, physical as well as sexual rest to permit of cure.

The Ministry of Health has devoted its energies largely to providing facilities for out-patient treatment. This was the obvious first step. If defaulting were not so frequent, it is probable that syphilis would now be very much diminished by this means. But with gonorrhœa, especially in the female, I am convinced that only a great increase in the provision of in-patient treatment will produce any appreciable improvement. Gonorrhœa in women appears to be steadily increasing in London—2136 applied for treatment in 1921, 2858 in 1926—and yet nothing practically has been done to provide them with the necessary in-patient accommodation. There were 150 beds at the London Lock Hospital in 1914. This number has not been increased; and no other hospital in London has made any adequate attempt to supply the deficiency. Certain hostels, it is true, have been provided where patients under out-patient treatment could sleep. Apart from the fact that rest and proper supervision cannot thus be provided, the numbers using these hostels have been too few to affect the main contention. I consider that at least 500 beds are required adequately to tackle the problem of gonorrhœa in women in London. Until this has been done it is difficult to see how one can possibly hope to stem the steady increase of gonorrhœa in both sexes that we are up against at the present moment.

It is to be hoped that the statement that the Government will oppose the second reading of the Corporation of Edinburgh's Bill is inaccurate. The Bill ought to have a fair chance. It is backed by the weight of medical opinion all over Scotland. Edinburgh is a favourable centre on which to base such an experiment. Obviously the scheme as at present administered in England is not the success we have the right, with all our hard work, to expect. We should learn much from the success or failure of the Edinburgh scheme. It is to be hoped that the Ministry of Health will not persist in its non possumus attitude, but will give the Bill the chance that it deserves.—I am, Sir, yours faithfully,

J. JOHNSTON ABRAHAM.

Harley-street, W., April 14th, 1928.

GASTRO-DUODENAL ULCERATION.

To the Editor of THE LANCET.

SIR,—It would be a calamity if the profession at large was lulled into a state of false security by such statements as "alkalosis is a bogy which need not be feared," especially when uttered in high places, and my excuse for reopening the correspondence on this subject is to emphasise the dangers alluded to by Dr. Hurst in his letters of March 3rd and 17th by recording in some detail the following experience which has occurred, aptly enough, in a patient undergoing treatment for duodenal ulcer on the lines laid down by Prof. MacLean and his associates.

Mrs. X, a woman of 48, had her right kidney removed for hydronephrosis in 1914. Two years later symptoms suggestive of duodenal ulcer made their appearance and continued off and on till 1924, when the diagnosis was confirmed by X ray examination, and she underwent a course of medical treatment at home under the direction of my colleague Dr. A. P. Thomson, who tells me that he made a note in April of the same year, "Cannot take alkalis well ? Kidney." The symptoms were not severe, and the u was free from albumin. She remained well for some mon being able to take alocol and a nightly dose of milk magnesia, but she then broke down again, attacks of typ ulcer distress alternating with periods of relative calm unti January of this year she heard of the results claimed by P MacLean and his associates. Under the impression that h in the outer darkness, we were unfamiliar with this rec development in ulcer therapeutics, she consulted a w known practising physician in London from whom detail the treatment were obtained, an opinion being expressed the consultation that her previous nephrectomy was nc contraindication. The complete régime was sent to private doctor, under whose care she entered a nursing h on March 13th. I saw her for the first time on Fri evening, March 16th, the treatment having then been progress four days. Toxic symptoms had appeared March 14th, when she complained of headache wh increased in severity during the next 24 hours, and the following evening she began to vomit her feeds. March 16th she appeared desperately ill; there was comp anorexia, constant nausea, and an inability to retain food, the headache remaining severe. At this time the u contained a moderate cloud of albumin, and granular c were fairly numerous in the centrifuged deposit. The bl pressure was 185/95. The vomit was acid, the readi being 26 for the free HCl, and 42 for the total acidity. removal of all alkalis and the substitution of rectal sal containing glucose and calcium chloride for mouth feed brought about a rapid improvement in her condition, within 24 hours she was free from urgent symptoms. blood-urea examined after 24 hours' starvation was 93·6 per 100 c.cm; a week later 69·1, and at the time of writ April 11th, 35. The urine became free from albu within 48 hours, and casts are no longer present. The u concentration test, carried out by Calvert's method April 6th, gave urea readings (*a*) 3·1 per cent. (*b*) 0·774 cent. The blood pressure also fell rapidly, and has 135/85 for the past fortnight.

I have recorded this case in detail because illustrates the possibility of occurrence of t symptoms from alkalis in a patient in whom renal function is normal by the usual tests at disposal, and because I cannot agree that no spe supervision or knowledge is necessary in carrying this particular line of treatment. Every practitio should be aware of the manifestations which m occur as a result of the administration of large d of alkali, and while symptoms of the severity of th recorded are admittedly rare, minor disturbances I submit, not uncommon. I have used Dr. Hur modification of Sippy's régime for the past seven ye with excellent results both in hospital and pri practice, but not infrequently have had pati especially in hospital who complained of nau slight headache, and even occasional vomiting, w were relieved by reducing the dosage of alkali o substituting the insoluble neutral tribasic phosph of calcium and magnesium.

I am, Sir, yours faithfully,

Birmingham, April 11th, 1928. T. L. HARD

THE PREVENTION OF PERITONEAL ADHESIONS.

To the Editor of THE LANCET.

SIR,—In a critical analysis[1] of a recent publica of mine on the prevention of peritoneal adhesi you call attention to the fact that it would be un to interfere with the fibrin-forming function of peritoneum since it is through this function that peritoneum limits the spread of infection by agglutination to one another of contiguous fi coated viscera. And you go on to say that the w "tacitly assumes that the average surgeon w desire to see a profuse flow of serous fluid em from his abdominal drainage-tubes, inserted peritonitis, at the expense of the fibrin-forming thereby infection-localising power of the peritone This increased lymph flow, you point out, pro a suitable medium for the growth of streptoc the common cause of peritonitis, and because v very fluidity prevents the migration of leucocyt

[1] THE LANCET, Jan. 21st, p. 144.

These suggestions and criticisms would be logical
d just if I had suggested the routine prevention
fibrin formation in peritonitis. In my paper I
licated a method, proved experimentally, for
eventing the encapsulation of drains inserted in
e normal peritoneum, and in the presence of a so-
led chemical peritonitis, produced by tincture of
line. I stated the opinion that the method had
ssibilities in the treatment of bacterial peritonitis.
the present time I am carrying on the second
ase of this work, dealing with the bacterial peri-
nitis. It is not my intention to prevent fibrin
rmation and thereby increase the area of peritoneum
volved in the infective process. I believe that it
uld vastly increase the mortality from peritonitis
re we routinely to prevent or interfere with fibrin
rmation. But in the virulent forms of peritonitis
idence of fibrin is frequently absent. We have
nd, experimentally, that in the most virulent form
the disease the fluidity of the exudate is greatly
reased, and there is not the slightest trace of
rin, as shown by a total absence of agglutination.
Under such conditions I believe that the use of
pertonic dextrose solution will not interfere with
most important of the normal defence mechanisms
the peritoneum. The flow from the drainage-tube,
tead of being a pure serous fluid, would contain a
ge percentage of toxic exudate. The drainage of
s toxic exudate, instead of permitting its absorption,
as much to be desired as in the case of thoracic
pyema. That the increased lymph flow provides
suitable medium for the growth of streptococci,
n this instance correct. But this increased lymph
v contains a considerable amount of dextrose.
has been shown by Kendall and others that the
ptococcus, as well as other types of virulent
hogenic bacteria, in the presence of a medium
taining dextrose, becomes converted into harmless
-producing organisms.

I am, Sir, yours faithfully,

hicago, April 4th, 1928. J. R. BUCHBINDER.

NASAL OBSTRUCTION AS A CAUSE OF DEAFNESS.

To the Editor of THE LANCET.

IR,—I think Mr. Macleod Yearsley must have
m understood me. I wrote nothing in deprecation
o resection. In fact, the second case to which I
rred in my letter was treated by the removal of
a ptal spur by an antiquated method which, although
it ave excellent results, was not comparable to a
su mucous resection. My experience has convinced
m that resection and the cautery may be supple-
m tary or alternative methods, or that either alone
m be clearly indicated. During the war I was
a pointed surgeon to a hospital reserved for officers
of he Air Force. One of the primary objects of the
ho ital was the treatment of nasal conditions; and
on of the first cases I treated was an officer who had
ha his tonsils and septum removed privately before
ad ission. He was sent into hospital because
pr nounced nasal obstruction was still evident.
Be n operations had been skilfully performed. The
re lt of a few cauterisations was to convert an
ap arent failure into a complete success. The
hi ory of that case has many times repeated itself.

n reply to the criticism that the use of the cautery
ne ssarily leads to the injurious destruction of the
se ting surface, I will describe the method I
en loy. My object is, of course, to produce not a
pa age but a scar which on shrinking will drag
th surface down to the bone. I use a fairly sub-
st tial platinum wire (about 1 mm. in diameter)
as cautery point. Owing to the movements of
th hand this creates a wound about 2 mm., or
po bly 1/10 in. in width. If a vertical section were
ma e through the middle of one of the nasal fossæ,
an a narrow strip of mucous membrane were removed
at he site of section, it would measure between 5 and 6 in., and the greater part consist of respiratory membrane. If the area which this represents be contrasted with the scar resulting from the use of the cautery, I submit that the effect of the latter is negligible. This reasoning would be fallacious if the second criticism were valid that the surface was injured over an extensive indefinite area round the site of cauterisation. Anyone can satisfy himself that this is not so by repeating an experiment which I made to verify this point. I split the end of a small wooden match and I wound the frailest fragment of cotton-wool round one of the limbs. I then dipped it in water and laid it horizontally on the side of my first finger with the naked limb uppermost. I found that I could cauterise the naked limb through without causing discomfort. A friend measured the distance of the cautery point from my finger at the conclusion of the experiment and as far as we could judge it was the 1/12 in. The experiment revealed the advisability of using a cautery at the lowest practicable temperature. The object of the wet cotton-wool was to prevent the wood conveying heat to the finger, and to ascertain if moisture in the nose was a contra-indication to the use of the cautery.

The necessity of cilia for the maintenance of drainage depends on the angle which the surface to be drained makes with the horizontal, and whether drainage is assisted or opposed by gravity. On the upper and lower surfaces of the turbinals and on the floor of the fossæ it is necessary; but on the smooth vertical surface of the turbinal its function must be limited to filtration. In private practice the ill-effects of treatment come under observation, and shortly before the war, in verifying a cocaine account, it transpired that I had anæsthetised 1700 cases in six months. I feel, therefore, justified in asserting that ill-effects resulting from the scientific use of the cautery are exceedingly rare. The desiderata are delicacy, and that neither manipulation nor examination should be made unless both hands and instruments are effectively sterilised. This applies to the application of the cautery, but particularly to the preparation of the nose, which involves touching cotton-wool, and foot-controlled basins, which I had in both consulting-rooms, are highly desirable. I have stood behind men drying the mucous membrane and would have regarded it as a miracle if it escaped injury. The conjunctiva, if anæsthetised, would not have been similarly treated, and yet it is hardly more sensitive.

I am, Sir, yours faithfully,

H. MACNAUGHTON-JONES.

Eton-avenue, Swiss Cottage, N.W., April 15th, 1928.

TONSILLECTOMY AND RHEUMATISM.

To the Editor of THE LANCET.

SIR,—Dr. Ogilvie and I were fully alive to the criticism to which we were exposed by the small number of our cases; not that our figures were liable to error, but that our conclusions from so small a series of cases might prove unconvincing. The difficulty in assessing the value of conclusions drawn from a small number of cases lies rather in the uncertainty that the cases were a "fair sample" than in the figures themselves; and Dr. Stallybrass, whose interesting criticism of our figures appeared in your issue of April 14th, will doubtless admit that calculations of probable error are themselves fallacious when applied to small numbers.

In the death-rates shown in Table II. of our paper (of 35 tonsillectomy cases 3 died (8·7 per cent.); and of 45 non-tonsillectomy cases 6 died (13·3 per cent.)). Dr. Stallybrass calculates a probable error of ±4·8 per cent. in a difference of 4·6 per cent. I suggest that in these figures there is no possible error, and that calculations of probable error are valueless. By his paraphrase of our Table IV. Dr. Stallybrass appears to have fallen into an error which invalidates his final criticism of our figures. Table IV. was as follows.

TABLE IV.—*Rheumatic Children.*

Heart condition.	Healthy throats.	Tonsils and glands.
	Number and percentage.	Number and percentage.
Normal (27 cases)	20 (74)	6 (20)
Damaged (20 cases) ..	9 (45)	9 (45)
Cardiacs (24 cases)	8 (33)	15 (62·5)

In his paraphrase Dr. Stallybrass substituted "normal tonsils" for "healthy throats"; but since of the 20 children, with normal hearts, who also had healthy throats, 15 had had their tonsils removed, it seems to me unfair to classify them as having normal tonsils. Nor can I agree with the criticism that "this shows that the figures are sufficient to indicate that rheumatic persons with normal tonsils are definitely less likely to have developed heart disease than those with diseased tonsils. . . ." Perhaps in view of the above Dr. Stallybrass will agree with me that rheumatic children who have had their tonsils removed are definitely less likely to develop heart disease than those who have retained diseased tonsils.—I am, Sir, yours faithfully,

Birmingham, April 16th. K. DOUGLAS WILKINSON.

LECTURERS ON SOCIAL HYGIENE.

To the Editor of THE LANCET.

SIR,—Owing to the numerous calls the British Social Hygiene Council are in need of the services of additional medical men: 1. Those who would be willing to leave London and to undertake from three to ten days' lecturing with public health films in the provinces. 2. Those with experience in popular speaking willing to address general industrial audiences on problems of social hygiene in London and the Home Counties area. Full particulars are given in your advertisement columns.—I am, Sir, yours faithfully,

A. H. HARKNESS,
Hon. Medical Secretary, British Social Hygiene Council.

Carteret House, Carteret-street, S.W., April 16th, 1928.

ALLEGED OVER-PRESCRIBING.

To the Editor of THE LANCET.

SIR,—You summarised last week (p. 776) a report presented to the East Sussex Insurance Committee, criticising the procedure adopted by the Ministry of Health in the case of a panel practitioner whose prescribing exceeded the average cost for the area. I should like to give the other side of the picture. I cannot see why anyone should object to having his panel prescribing criticised by the Regional Medical Officer as often as may be considered necessary. Such an interview is vastly preferable to having one's already meagre pay docked by the Minister, or even having to attend a panel committee at a distance. Give me the R.M.O every time, especially if he happens to be the shrewd and helpful Scotsman who came down to me the other day. I do not think it is generally realised that it is one of the functions of the R.M.O. to try to make a working success of a somewhat unsatisfactory and difficult service, turning at times a blind eye to the letter of the law. These officers appear to be liaison officers rather than instruments of the unlovely panel machine. As a result of the kind advice of the R.M.O. and of a desire to save my pocket from being mulcted, I have altered my standard of prescribing. When a patient requires a valuable drug which is not in the Pharmacopœia I give him a private prescription and tell him to buy it for himself. In this way I have greatly reduced my drug bills, but where the patient is too poor or too mean to buy good drugs for himself, it takes him longer to get well, and off the hands of his society.—I am, Sir, yours faithfully,

April 17th, 1928. EAST SUSSEX G.P.

Obituary.

RICHARD LANE JOYNT, O.B.E., M.D. DUR F.R.C.S. IREL.

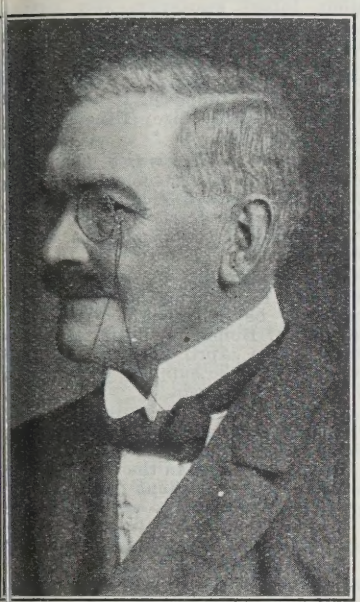
THE death of Mr. Lane Joynt occurred in Du at Easter after a few days' illness, at the age of Born in Dublin, the son of a solicitor, he was educa at Trinity College, where he graduated in 1890. proceeded to the Fellowship of the Royal Colleg Surgeons in Ireland in 1894, and subsequently was many years a member of the Council of that b Early in his professional life he was appointed assis surgeon to the Meath Hospital and for the last or five years of his life was its senior surgeon. Du all his hospital career he performed the routine du of a hospital surgeon punctiliously and competen but he was always specially interested in mechan problems. Radiography came into use while he still a junior surgeon, and he was at once attracte its great possibilities. As one of the early wor with X rays his hands became gravely affected dermatitis and for a time he was unable to per any ordinary surgical work, though nothing c make him idle. So bad did his condition become the question of double amputation was raised, but rigorous methods fortunately proved successful, a series of grafting operations carried out a yea two ago left him again with the full use of his ha This was to him of the greatest importance, for he a mechanic of rare skill, equally at home in carpe and metallurgy; an example of his ingenuity is in the note on Skin-grafting sent to THE LA shortly before his death and published on p. 81 this issue. His special choice in surgery was treatment of injuries of bone and of deformities, he was one of the early surgeons to carry out plating of fractures with metal plates. During war his real forte was found in the planning and m facture of surgical and orthopædic apparatus, ar his own workshops he organised the manufactu splints and other apparatus for the treatmen deformities, obtaining the help of many wi volunteers. Subsequently his work was offic recognised by the War Office, and he was appoi Inspector of Orthopædics with the rank of Li Colonel. His particular task was the devisin proper apparatus for dealing with unusual deform and in the more difficult cases he not only devised completed the manufacture of the article with his hands. In work of this kind surgeons throughout kingdom were glad to have his assistance.

Apart from his professional work Joynt had m interests. He loved handicrafts, he was a pi motorist and an expert yachtsman. Furthermo was a man of wide general reading, and thoroug companionable, never seeking publicity and rating his claims high. By his death the profe loses a good surgeon, a craftsman, and a ma principle.

JOHN STEPHEN McARDLE, M.CH. R.U.I F.R.C.S. IREL., J.P.

Mr. J. S. McArdle died at his residence, Me square, Dublin, last Saturday, after a long painful illness. Sixty-nine years of age, he was in Dundalk and received his early education Mary's College in that town. His immediate inte in boyhood was to become a jockey, and he was act apprenticed for a time to a trainer of race Though this idea had to be abandoned in fav his father's profession of medicine, he retained end of his life an enthusiasm for the turf. studying medicine at the Cecilia-street (Ca University) School of Medicine in Dublin he re the licences of the Royal Colleges of Physician of Surgeons at the early age of 21, and beca Fellow of the Royal College of Surgeons in I in 1884. While still a very young man h appointed to the surgical staff of St. Vincent's Ho

which institution he remained attached for the rest his life. He was also professor of surgery in the cilia-street School, and in 1903 was elected a Fellow the Royal University, which in 1900 had conferred him the honorary degree of Master of Surgery. hen the National University replaced the Royal was appointed professor of surgery in the Dublin llege. In his early days he contributed frequently the medical journals, and he wrote some useful books for students; but in later life the calls of practice were too many to leave him leisure for writing.



MR. J. S. MCARDLE.
Photograph by Lafayette, Dublin.

"As an operating surgeon," writes a colleague, "McArdle early made a name for himself, and for the last 40 years he has been one of the best known surgeons in Ireland. He was quick in decision, clear in emergency, and precise in execution. His forceful character inspired confidence. As a teacher he was probably at his best. His clearness, his force, his humour le his lessons to be remembered. But apart n his skill as a surgeon and his capacity as a her, McArdle had a great personality. In his pany one knew that he was something out of the mon. His joy of life, his verve, his greatrtedness, his boyishness, made him friends everyre and in every company. There were few men in profession who had so many friends, and he was oyal to his friends as they were to him. Ireland -day the poorer by the loss of a generous, a kindly, a lovable son."

r. McArdle was twice married, having two sons two daughters. He was a member of the Senate he National University of Ireland and President he Irish Medical Association.

CAVENDISH FLETCHER, M.B. LOND.

HE death of Dr. Fletcher on March 3rd, after a f illness, at the age of 45, removes an able exponent linical pathology. He was born in London, the of Alfred E. Fletcher, sometime editor of the *ly Chronicle*, and was brought up in an atmosphere evotion to justice and fair play which remained acteristic of him throughout life. He went to son's Grammar School and London University, ng his clinical studies at Westminster Hospital, which he qualified M.B., B.S. Lond., in 1906. r a house appointment there he went on to the nty Asylum at Leek, and the Union Hospital at field, developing at these places a taste for clinical ology, which led to an appointment as pathologist he Royal Southern Hospital at Liverpool. In , however, he joined the staff of the (London) oratories of Pathology and Public Health, and he last eight years held the senior post of Director. he same time he was honorary pathologist to the Edward Memorial Hospital at Ealing. "Much he intense labour which Fletcher devoted to technical problems, will," writes one of his colleagues, "never be known to the world, but his co-workers gained immense help from him. Engrossed in the pursuit of clinical pathology, his sole preoccupation was concerned with its advancement, with perfecting its technique, and with simplifying the means of attaining this. Thorough master of all the present-day ramifications of pathology, he excelled especially as morbid histologist, his verdict on the interpretation of microscopic sections being rarely falsified by the subsequent events." Eight or nine years ago, in collaboration with Prof. Hugh MacLean, he published a little book which aimed at guiding the practitioner in his relations with the pathological laboratory and at solving the difficulties, so far as they can be solved, of a scheme in which pathologist and laboratory are not in close proximity to practitioner and patient. Dr. Fletcher married Ellen, a daughter of Mr. R. Strain, and sympathy is felt with his widow, left with the care of a son and a daughter.

EDGAR WILLIAM WILLETT, M.D. OXF., F.R.C.S. ENG.

WE regret to record the death of Dr. Edgar Willett on April 13th after a brief illness. He was born on April 5th, 1856, at Brighthelmstone, as it was then called, where his father, Mr. Henry Willett, a wealthy brewer, was a well-known figure for many years, and bequeathed to the town a valuable collection of ceramics and other exhibits, now housed in the museum adjoining the Brighton Pavilion. To his father Edgar Willett owed the early training in natural history, and the interest in various branches of art which remained for his life-time a valuable inheritance. He went to school at Wellington, and proceeded to New College, Oxford, as a commoner, whence he took a 1st class Natural Science degree in 1879, became M.B. in 1885, and M.D. in 1904, having been made a Fellow of the Royal College of Surgeons in 1888. His choice of medical school fell on St. Bartholomew's, where his cousin, Mr. Alfred Willett, had recently been appointed full surgeon. After serving as his house surgeon, Edgar Willett became assistant anæsthetist under Mr. J. Mills, and succeeded Mr. Richard Gill on his retirement. He specialised as an anæsthetist in London for many years, residing in Queen Anne-street, and was President of the Society of Anæsthetists in 1905–06. He was also assistant surgeon to the Metropolitan Hospital, and surgeon to the Belgrave Hospital for Children. Not a voluminous writer, he contributed various articles to the St. B.H. Reports, and to the Transactions of the Pathological Society.

Edgar Willett retired from practice about 1906, and lived at a charming house in Worth Park, Sussex, where he occupied himself in local affairs, and was on the county council of East Sussex. He retained a keen interest in prehistoric archæology, and contributed articles on Flint implements to the journals of the Sussex Archæological Society and the Anthropological Institute. He was one of the original recruits in the London Volunteer Medical Corps, and was commissioned as Captain. Retiring with this rank he served again during the war chiefly at a hospital in Croydon, and was retired as Major, R.A.M.C., after the Armistice. In 1923 he bought a house at Hartfield, which he filled with treasures of furniture, pictures, and pottery, largely inherited from his father's extensive collections.

The friend and contemporary, to whom we owe most of these biographical details, remarks that Willett always maintained touch with his old hospital, and had a wide circle of old Bart.'s friends. Until the last few years his house was a centre of warm hospitality, but for some years his powers had been on the wane, and an increasing deafness impaired the great social qualities which had distinguished him. Never athletic or good at any game, he remained a good shot to his old age, and though he never hunted he was constantly to be found on foot at meets and covert sides. He was unmarried.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a recent examination the following candidates were approved :—

DIPLOMAS IN PUBLIC HEALTH, HYGIENE, AND TROPICAL MEDICINE AND HYGIENE.

Part I.—Baharsing Jagatsing Ajwani, Manmohan Singh Batra, *Colin Fraser Brockington, Bertha Margaret Butters, Ryder Carrel Dracup, Ishac Kirolos Gayid, Margaret Ann Glass, Nityaranjan Gupta, *Girgis Abdel Messih, Jean Hall Morton, Robert Arthur Welsford Procter, Effie Scott Stephen, Jagan Nath Vasudeva, Donella Anna Ferguson Watson, Dorothy Watterson, Percival Clarence Wickremesinghe, and *Koh Cheang Yeo.

* Distinguished.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a quarterly meeting of the Council held on April 12th, Sir Berkeley Moynihan, the President, in the chair, the John Hunter Medal in bronze with the Triennial Prize of £50 was awarded to Mr. Victor Ewings Negus, M.S., F.R.C.S., for his investigations into the comparative anatomy and physiology of the larynx and the anatomy of the bronchi in their relation to surgery.—Mr. Charles Thurstan Holland, Ch.M. Liverp., and Sir Matthew Henry Gregson Fell, K.C.B., C.M.G., Director-General of the Army Medical Service, as Members of the College of 20 years' standing, were elected to the Fellowship.

No award of the Jacksonian Prize for the year 1927 was made. The subject of the essay for the Jacksonian Prize for 1929 will be the Pathology, Diagnosis, and Surgical Treatment of Diseases of the Salivary Glands.

A letter was read from the Canadian Medical Association approving the revised scheme for conducting Primary Fellowship Examinations in Canada, and conveying the thanks of the Executive Committee of that Association for the very efficient and generous provisions made. An account of the scheme will be found on p. 831.

Diplomas of Member were conferred upon the following who have passed the requisite examinations and have now complied with the by-laws of the College, viz. : A. D. W. Cooke, M.B., B.S. Durh., Durham and St. Mary's ; S. McGladdery, St. Bart.'s ; H. H. Mahmood, M.B., B.S. Punjab, Punjab and Middlesex ; J. W. Notley, Birmingham ; and Joan M. Oldaker, Royal Free.

The Hallett Prize at the Primary Fellowship.—The Council, being desirous of showing their appreciation of the services of Sir Frederic Hallett in connexion with the examinations for the Fellowship and the Licence in Dental Surgery during the long period of 50 years, from 1877 to 1927, and Sir Frederic Hallett having expressed a wish that the personal gift which it was proposed to make to him should take the form of the endowment of a prize to bear his name, it has been agreed that stock be purchased by the treasurers of the College on behalf of Sir Frederic Hallett and that the interest from the fund so established be expended on a prize called the Hallett Prize, to be awarded under the following regulations : The Hallett Prize shall be open to candidates admitted for the first time to the Primary Examination in Anatomy and Physiology for the Fellowship conducted by the board of examiners in this country. The Prize at each examination shall consist of a sum of 5 guineas with a certificate of the award of the Prize. The Prize shall be awarded to the eligible candidate, if any, obtaining the highest marks, who shall have reached a standard considered by the examiners sufficiently high to justify the award of the Prize. If two or more candidates are found to have reached the required standard and to have been allotted the same number of marks, being the highest obtained by any eligible candidate, it shall be open to the examiners to take such steps as they may think desirable to enable them to adjudicate in the matter.

ST. MARY'S HOSPITAL INSTITUTE OF PATHOLOGY.—A course of lectures on Pathological Research in its Relation to Medicine will be held in the bacteriological department of this institute at 5 P.M. on Thursdays, from April 26th to June 14th inclusive. The first lecture, on the Bactericidal Power of the Blood, and the Appraisement of the Value of Therapeutic Agents, will be given by Sir Almroth Wright, F.R.S., principal of the institute, on April 26th. The other lecturers will be Prof. D. W. Carmalt-Jones (Iodine in Relation to Goitre), Prof. E. C. Dodds (the Ovarian Hormone), Prof. Hamilton Hartridge, F.R.S. (Poisoning by Coal Gas and Products of Combustion), Prof. R. H. A. Plimmer (Some Recent Researches on Vitamins), Dr. G. V. Anrep, F.R.S. (Pathology of Conditioned Reflexes), Sir Oliver Lodge (The Uses we make of the Ether of Space), and Dr. Paul Fildes (Principles of the Treatment of Tetanus with Antitoxin). The lectures will be open without fee to all members of the medical profession and to students n medical schools.

AUXILIARY R.A.M.C. FUNDS.—The annual mee of the members of the Auxiliary Royal Army Medical C Funds will be held on Friday, April 27th, at 2.30 P.M 11, Chandos-street, Cavendish-square, London, W. 1.

BRITISH ORTHOPÆDIC ASSOCIATION.—The Sp meeting of this association will be held in Paris on Fr and Saturday, April 27th and 28th.

ROYAL SANITARY INSTITUTE.—A sessional mee will be held on Friday and Saturday, April 27th and in the Guildhall, Worcester. Subjects of discussion include river pollution, infant mortality, and activ sludge. On Saturday, May 5th, at 10 P.M., at the Guild Preston, a discussion on the present position of the w supply will be opened by Prof. F. E. Wynne, Dr. R. V Clark taking the chair. In the afternoon visits wi paid to places of interest. Those proposing to attend sh notify Dr. F. A. Sharpe, Health Office, Tithebarn-st Preston, not later than April 27th.

UNIVERSITY OF LONDON: *University College.* course of three lectures on the Pharmacological Evid for Modern Methods of Treatment will be given by Dr. Burn at University College, Gower-street, W.C., on Tues Wednesday, and Thursday, May 1st, 2nd, and 3rd, at 5 Admission free without ticket.

UNIVERSITY OF BIRMINGHAM.—A course of William Withering Memorial Lectures on Industrial Mal and Factory Hygiene will be delivered by Sir Th Legge at the Medical School Buildings, Edmund-stree 4 P.M. on Wednesdays from April 25th to June inclusive. Admission cards will be supplied on applic to the acting Dean, Prof. J. C. Brash.

INDIAN MEDICAL SERVICE.—The annual di of the I.M.S. will be held at the Trocadero Restau London, on Wednesday, June 20th, at 7.15 P.M., M General Sir Richard Havelock Charles in the chair. Fu particulars may be had from the joint hon. secre Major Sir Thomas Carey Evans, M.C., at 31, Wim street, London, W. 1.

BRITISH EMPIRE CANCER CAMPAIGN.—Sir J Bland-Sutton (Vice-Chairman) presided at the quar meeting of the Grand Council of the British Empire C Campaign held on April 17th. On the recommendati the Scientific Advisory Committee the Grand Co approved the following grants : £200 for one yea Dr. Louis Cassidy, to be applied through the new Nat Cancer Campaign (Ireland) ; £300 for one yea Mr. Harold Burrows, working at the Cancer Hospital (F £300 to Mr. C. F. W. Illingworth for one year for wo be carried out at Edinburgh University ; and £1000 fo ensuing year for work to be carried out under the s vision of Mr. F. C. Pybus, at Newcastle-on-Tyne. O recommendation of the Executive Committee the G Council also granted a sum of £400 to St. Mark's Hos City-road, and £100 to the Medical Society of Lo towards expenses incurred in the preparation and pu tion of statistical investigations recently carried ou that Society. The Grand Council received reports the various committees in charge of the preparation the International Conference on Cancer, to be held d July. Already 40 acceptances have been received foreign representatives in all parts of the world, and 100 delegates have been nominated by the leading u sities, medical schools, and scientific and medical soc of the British Isles and the British Dominions overse

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

REASSEMBLY OF THE HOUSE OF COMMONS.

THE House of Commons reassembled after the E recess on Tuesday, April 17th. The House of reassembled on Thursday, April 19th.

THIRD PARTY INDEMNITY INSURANCE BILL.

In the House of Commons on Tuesday, April 17th ATKINSON asked leave to introduce a Bill to provid the direct discharge of third party liability by insurers. explained that the object of the measure was to ma the duty of an insurance company in so far as they liable for third party claims to pay those claims dir the injured person. It did not entitle the claimant to proceedings direct against the insurance company fo purpose of establishing liability or the amount of lia but once that liability was admitted, or established by proceedings, the insurers were then to hold the mon trust for the injured person and were under no oblig to pay the money over direct.

Leave to introduce the Bill was granted without a di and the Bill was read a first time.

THE PETROLEUM AMENDMENT BILL.

The Petroleum (Amendment) Bill was considered on port on April 17th.

On Clause 4 (which makes regulations as to classes of roleum likely to be dangerous or injurious to health).

Mr. HARDIE moved an amendment giving the Home retary power to prohibit the sale or use of petroleum rit which he might, by Order, declare to be so dangerous injurious to health that precautions for the protection persons employed or engaged in handling or using such roleum spirit were impracticable. He said that the endment referred to lead tetraethyl in petrol.—Sir W. YNSON-HICKS (Home Secretary) said that he would ept the amendment. Lead tetraethyl in petrol was now subject of an inquiry, and if the Home Secretary should, a result, declare that this particular spirit was injurious health, the amendment would be useful.

The amendment was agreed to.

The report stage was completed and the Bill was read hird time.

HOUSE OF COMMONS.

TUESDAY, APRIL 17TH.

Dysentery in Sinarango Prison Camp.

Mr. DAY asked the Secretary of State for the Colonies number of prisoners who were affected by dysentery he Sinarango prison camp, Malaita, while awaiting trial the murders that occurred last October; and the number deaths which occurred.—Mr. AMERY replied: 71 cases lysentery have occurred among the prisoners and there e been eight deaths. Seven cases were still under atment on April 2nd.

Voluntary Venereal Disease Clinics in Scotland.

Mr. BUCHANAN asked the Secretary of State for Scotland number of towns in Scotland of a population of 10,000 over which had no voluntary clinics for dealing with the blem of venereal disease; if he could give the names of se towns; and if he was at present taking any steps to e those local authorities to set up clinics.—Sir JOHN MOUR replied: The number of towns in Scotland with ensus population of 10,000 or over, and without a public ic for dealing with venereal diseases is 26, of which seven e a population of 20,000. These burghs, in order of ulation, are: Clydebank, Falkirk, Airdrie, Rutherglen, mbarton, Port Glasgow, Inverness, Musselburgh, Hawick, khaven, Methil and Innerleven, Rothesay, Dunoon, denbeath, Renfrew, Saltcoats, Peterhead, Galashiels, nstone, Alloa, Kirkintilloch, Barrhead, Montrose, Loch-y, Fraserburgh, Bo'ness, and Gourock. In three of se burghs—Falkirk, Inverness, and Rutherglen—pro-on of a venereal disease clinic is in course of being made, under active consideration. Four of these burghs—drie, Port Glasgow, Musselburgh, and Gourock—are so veniently situated for the clinics of adjacent larger towns not to require independent provision. The remaining burghs are served to a greater or a less extent by the rest available clinics of other towns. In 11 of these ghs the Scottish Board of Health have not thought the stion of providing a local clinic to be sufficiently urgent call for pressure by them upon the Local authorities, ing regard to the facilities available in neighbouring ns. In the case of the remaining eight burghs—lebank, Dumbarton, Hawick and Galashiels, Peterhead Fraserburgh, Saltcoats and Kirkintilloch, the question stablishing a burgh clinic or a joint clinic has been sidered by the responsible local authority, and remains n. The development of the schemes in all areas is being fully watched and reviewed by the Board.

Medical Diary.

SOCIETIES.

AL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, April 23rd.—8 P.M., ODONTOLOGY. Paper: Dr. Alexander Livingston: Further Experiments on the Permeability of Enamel. Casual Communications: Mr. W. Rushton: Injection of Alcohol for Neuralgia and its Sequel. Mr. Lewin Payne: A Paste for Obtunding Hypersensitive Dentine.

TUESDAY.—5 P.M., MEDICINE. Paper: Prof. Snapper (Amsterdam): The Rôle of the Kidney in Non-renal Disorders. Demonstration: Dr. A. F. Hurst and Dr. P. J. Briggs: Radiological Demonstration Illustrating Unusual Alimentary Disorders.

THURSDAY.—8.30 P.M., UROLOGY. Clinico-pathological Evening.

FRIDAY.—4.30 P.M., DISEASE IN CHILDREN (at the London Hospital, E.). Tea will be served at 4.30 P.M. Cases will be shown.—8 P.M., EPIDEMIOLOGY. Paper: Dr. Allan C. Parsons: Post-encephalitis and its Problems.—8.30 P.M., ELECTRO-THERAPEUTICS. Short Papers: Dr. R. W. A. Salmond: Observations on the Movements of the Duodenal Contents, with Special Reference to Antiperistalsis and Pyloric Regurgitation. Dr. Bathurst: Treatment of the Incontinence in Women.

ROYAL SOCIETY OF ARTS, John-street, Adelphi.

WEDNESDAY, April 25th.—8 P.M., Mr. J. M. Ritchie, Ph.D.: The Education and Training of the Blind.

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, April 25th.—3.30 P.M., Dr. J. B. Alexander: Early Signs and Symptoms of Rheumatic Infections.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, W.

THURSDAY, April 26th.—8.30 P.M., Dr. John Glaister, Jun., Barrister-at-law: Hair: Considered Medico-Legally.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, April 27th.—8.30 P.M., a Paper will be read by Dr. Archibald Leitch on Syphilis in Relation to the Ætiology and Diagnosis of Malignant Disease.

ILLUMINATING ENGINEERING SOCIETY.

TUESDAY, April 24th.—6 P.M. (in the Home Office Industrial Museum, Horseferry-road, Westminster, S.W.), Inspection of Lighting Exhibits. 6.30 P.M., Discussion on Artificial Light, to be opened by Mr. J. S. Dow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ST. MARY'S HOSPITAL INSTITUTE OF PATHOLOGY, Paddington, W.

THURSDAY, April 26th.—5 P.M., Sir Almroth Wright, F.R.S.: The Bactericidal Power of the Blood and the Appraisement of the Value of Therapeutic Agents.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham.

MONDAY, April 23rd.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

On Tuesday and Friday, at 2.30 P.M., there will also be demonstrations of Throat, Nose and Ear and Medical Cases (Children) by Mr. W. Ibbotson and Dr. C. E. Sundell respectively.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, April 23rd, to SATURDAY, April 28th.—CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, Victoria Park, E. Tues., 10 A.M., Ward Round by Dr. V. S. Hodson. 2 P.M., O.P. Demonstration. The practice of the hospital is open for the day, and the above clinics are free to medical practitioners.—HOSPITAL FOR DISEASES OF THE SKIN, Blackfriars-road. Special Course, afternoons only (second week).—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. Wed., 5.15 P.M., Dr. Heald: Lecture-demonstration.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology.—LONDON SCHOOL OF TROPICAL MEDICINE, Endsleigh-gardens, W.C. Tues., 2 P.M., Lecture-demonstration by Dr. Carmichael Low. Thurs., 2 P.M., Lecture-demonstration by Dr. Manson-Bahr. Further particulars from the Secretary, Mayfair 2236.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 27th.—4 P.M., Dr. Dan McKenzie: Dental Cysts.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 24th.—4.15 P.M., Mr. A. H. Burgess: Renal Tuberculosis.

FRIDAY.—4.15 P.M., Mr. G. Jefferson: Demonstration of Neurological Cases.

Appointments.

ALLAN, J., M.D., B.Ch. Edin., D.P.H., has been appointed Ophthalmic Surgeon at the Downham (L.C.C.) Treatment Centre.

AMYOT, T. E., M.B., B.S. Durh., a Medical Referee under the Workmen's Compensation Act for Chester, and Holywell, Flint, and Mould Circuits.

BAIRD, J. E., M.B., Ch.B. Belf., Medical Officer to the Holt Line.

LAMONT, D. C., M.B., Ch.B. Edin., D.P.H., Medical Officer of Health, City of Lincoln.

MARTYN, F. D., L.R.C.P. Lond., M.R.C.S., Certifying Surgeon under the Factory and Workshop Acts for Sutton in Ashfield.

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital, Vauxhall Bridge-road, S.W.—Temp. Non.-Res. H.S. At rate of £150.

Alton, Hants, Lord Mayor Treloar Cripples' Hospital and College. Second Asst. Res. M.O. £300.

Basingstoke, Hants, Park Prewett Mental Hospital.—Second Asst. M.O. £450.
Birmingham and Midland Ear and Throat Hospital.—Asst. Surg. O. £200.
Birmingham City Infectious Diseases Hospitals, Little Bromwich.—3rd Asst. M.O. £350.
Bournemouth, Royal National Sanatorium for Consumption, &c.—Laryngologist.
Bristol General Hospital.—Pathologist and Curator of the Museum. £500.
Bristol Royal Infirmary.—Hon. Surg. in charge of Ear, Nose and Throat Dept.
British Social Hygiene Council, Carteret House, Westminster, S.W. Lecturer on V.D. &c.
Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—2nd Res. H.S. At rate of £75.
Chelmsford, Administrative County of Essex.—Two Asst. County M.O.H.'s. Each £600.
City of London Hospital for Diseases of Heart and Lungs, Victoria Park, E.—M.O. At rate of £100.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. and Whole-time Cas. O. Each at rate of £125.
Exminster, Devon Mental Hospital.—Jun. Asst. M.O. £300.
Farringdon General Dispensary, Holborn-circus, E.C.—Hon. Phys.
Fiji Government.—Dist. M.O. £500.
Glasgow Royal Infirmary.—Deputy Med. Supt. and Sen. Med. Resident. £200.
Gloucestershire Royal Infirmary.—Asst. H.S. At rate of £120.
Golden-square Throat, Nose and Ear Hospital, W.—Hon. Consulting Ophth. S. Also H.S. £100.
Hospital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.
London Hospital, E.—First Asst. and Reg. to one of the five Surg. Firms. £300.
Newcastle-upon-Tyne, Education Committee.—Asst. Sch. M.O.
Rotherham Hospital.—H.P. £180.
Royal Eye Hospital, St. George's-circus, Southwark, S.E.—Res. H.S. and Asst. H.S.
St. John's Hospital for Diseases of Skin, Leicester-square, W.C.—Hon. Asst. Phys.
St. Mary's Hospital, W.—Surg. in charge of Out-patients.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—3rd Anæsthetist. At rate of £25.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—Registrar. £100.
Stoke-on-Trent, City Education Committee.—Asst. Sch. M.O. £500.
Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Anæsthetist, Hon. Asst. Aural S. and Hon. Asst. Orthop. S. Also Asst. H.P. £125.
Walsall General Hospital.—Sen. H.S. At rate of £200.
York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Chaddesley Corbett (Worcestershire) and Crowborough (Sussex).

A vacancy is announced for a Medical Referee under the Workmen's Compensation Act for Bridgend County Court. Applications should reach the Home Office, Whitehall, S.W., not later than May 5th.

The Home Secretary gives notice that he is considering the appointment of a Medical Referee under the above Act for the district of the Bridgend County Court (Circuit No. 30). Applications for the post from duly qualified Medical Practitioners with surgical experience resident in, or in the neighbourhood of, Bridgend should be addressed to the Private Secretary, Home Office, Whitehall, London, S.W.1, and should reach him not later than May 5th, 1928.

Births, Marriages, and Deaths.

BIRTHS.

DE VILLIERS-PRITCHARD.—On April 17th, at 9, John-street, Mayfair, to Audrey, wife of Dr. C. W. de Villiers-Pritchard—a son.

MILLIGAN.—On April 15th, at Norfolk-square, W., the wife of Norman Milligan, M.B., of Royston, Herts, of a daughter.

MONTGOMERY.—On April 6th, at Foxhall, Osborne Park, Belfast, the wife of Dr. F. P. Montgomery, of a daughter.

MARRIAGES.

BARKER—JOHNSTON.—On Thursday, April 12th, at the Parish Church, Whitstable, Alan Barker, M.B., B.Chir., to Margery Lulu, elder daughter of Mr. J. R. J. Johnston, I.S.O., and Mrs. Johnston, Thatch House, Whitstable.

DEATHS.

PACKMAN.—On April 8th, at a nursing home, Alfred Charles Augustus Packman, M.D., J.P., for 41 years in practice at Rochester, aged 64.

SATCHWELL.—On April 8th, at North Curry, Somerset, Hubert John Satchwell, F.R.C.S.I., in his 60th year.

SHIACH.—On April 12th, suddenly, at Paris, Gordon Reid Shiach, L.D.S. (Edin.), of Rosebrae and Ardgilzean, Elgin, aged 61.

WILLETT.—On April 12th, at Spyways, Hartfield, Edgar William Willett, M.D., F.R.C.S., aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstract

TREATMENT OF GUNSHOT WOUNDS

AND THE IMPROVEMENT THEREOF BY AMBROISE PA IN THE CAMPAIGN OF FRANCIS I. AGAINST CHARLES V. (1536–1544).*

BY THEODORE MEYER-STEINEG,
PROFESSOR OF THE HISTORY OF MEDICINE IN THE UNIVERSITY OF JENA.
(*Translation by* F. J. FRANKAU.)

THE discovery and introduction of firearms raised questions not only for generals but for everyone dire or indirectly connected with warfare, including the med man. The latter recognised very soon that the wou caused by the new weapons, whilst similar in several resp to the injuries caused by the arms hitherto in use, displa a number of special features. But, as not infreque happens with a new problem of this sort, the judgm on these special features went far beyond the mark. A fi opinion, based on many crass errors, was arrived at, though these errors ought to have been clearly obviou the eyes of an unprejudiced medical man, they brou under their spell such a large circle of otherwise not uncri minds that, even when regard is had to the condition those days, we are to-day faced with an enigma.

Perhaps the extraordinarily slow spread of the new in tion contributed to the obstinacy of these opinions. F took nearly 200 years from the Battle of Crécy (1346 which field guns were used for the first time in any quan until portable firearms were universally introduced armies. And so it was not until the end of the fifte century that the increased numbers of wound cases affo the surgeons proper opportunities to observe the new fe of wounds and to exchange views about them.

Earliest Methods of Treatment.

A German, Heinrich von Pfolspeundt, in his work (1 entitled "Bündth-Ertzney," was the first to treat of powder, balls, and the wounds caused by them. An the work of another German author, Hieronigmus Brunschwig (1497), entitled "The Book of Wound Medici the view is for the first time expressed that gunshot wou are "poisoned" by the gunpowder and should be tre accordingly. Having regard to the paucity of his orig remarks, it is to be assumed that Brunschwig is only reta the opinions he gathered from others. In any case i erroneous view was widespread about the turn of fifteenth century, even in countries where his work scarcely have been known. Yet alongside of this p partial opinion wider views of other surgeons are to found. The latter consider gunshot wounds as injurie three sorts: contusion, burning, and poisoning.[1] Fore amongst those adopting this point of view was the Ita Vigo [2] (about 1460 to 1517), who by his authority not influenced the theoretical views of his contemporaries, very likely also the practical procedures which surg followed as a result thereof. The treatment advisec him and, which he announces with pride, was based his own very comprehensive experiences, displays abov else an endeavour to free the "poisoned" wounds of po For this purpose they should in the first place be b with a red hot iron (candenti ferro decoquere), or Egyptian salva, prepared according to Avicenna's pres tion, should be applied (unguentum ægyptiacum descript Aviccennæ administrare), or instead of this the wo should be burnt with boiling oil of the Sambucus (ferv oleo sambucino cauterizare), "for the cauterisation pro the patient against putrefaction of the wounds, as it the poison of the gunpowder." Not for a single mo

* Ambroise Paré was born in 1510 at Bourg-Hersent, Laval (Dép. Mayenne). He trained first as a barber and as a surgeon at the Hotel Dieu. In 1536 he took pa Francis I.'s campaign under de Montejan, and four years was promoted "maître barbier." After participating in fu campaigns he became one of the "chirurgiens ordinaires Henry II. in 1552, and was admitted to the "Collège de Côme" as "maître en chirurgie." Then followed dis with the Faculty of Medicine of Paris, as they tried to pr the publication of his writings. On St. Bartholomew's (1572) he only escaped with his life through King Charles whose "premier chirurgien" he was, affording him his per protection. Henry III. named him as a "conseiller." died in 1590, having served as privy surgeon to four kin succession, highly respected, but to the last opposed, openly, at any rate in secret, by the medical faculty.

[1] Contusion: "ratione rotunditatis instrumenti," Bu "ratione igneitatis," and Poisoning "ratione pulveris."

[2] Giovanni da Vigo, Practica in arte chirurgica copiosa. Lib. III., Tract. II., Cap. III. De vulnere facto ub instrum quod bombard nuncupation.

d it occur to Vigo, or to the many others who acted cording to his advice, that this procedure involved a ich more dangerous and deep-seated burn in addition to e serious and direct injuries to the tissues caused by the ot itself. And this, notwithstanding the fact that according the universal report of almost all writers, the mortality wounded persons who had been treated in this was was traordinarily heavy. The conclusion come to was simply at the poisoning of the wounds by the gunpowder was so tent that, notwithstanding the application of the best nedies, it destroyed the body.

Through these opinions the far saner and less drastic ethods of treatment of other surgeons were entirely driven to the background. For instance, the above-mentioned er. Brunschwig had proposed pushing a "rope of hair" rough the wound channel, drawing it backwards and rwards and thereby extracting the poisonous powder m the wounds. Or, if the wound did not then commence suppurate, a strip of bacon having one end rubbed with fat should be introduced into the wound passage, "so it ll attract all poison to itself and no poison will remain the cavity, and it will make the cavity suppurate." For bsequent treatment salves and plasters of various sorts re recommended. A special question arose in those ses in which the missile still remained in the body. unschwig had recommended that after widening the annel of the shot the ball should be extracted with llet forceps or with an instrument named from its shape stork's beak." Gersdorff [2] used a much larger assortment instruments; a long bullet spoon, called "hock," a ring tool to screw into a deep-seated ball, a thick-toothed ir of tongs called "snake," or a straight pair of tongs th block ends (Klotzzange).

In the works of the many other surgeons who wrote on e treatment of gunshot wounds, we find but very few riations from this procedure. Through Vigo the opinion to the poisoning of wounds became the paramount one d the common belief of surgeons, so that the "freeing e injury of poison" and the methods prescribed by Vigo that behalf appeared to be the most important duty of e surgeon.

An Accidental Discovery.

Even Ambroise Paré, a usually very critical person, admits thout qualification that he at first accepted this early ew as to the poisoned nature of gunshot wounds and had llowed the treatment prescribed by Vigo, though not ite without scruples. It was only thanks to an accident at he realised the error of his opinions and the harmful ture of the practice following from them. He describes this ite modestly in his work: "La méthode de braicher les ayess faïctes par hacquebutes et aultres bastons à feu: de celles qui sont faictes par fléches, dardz, et semblables: ssy des combustions spécialement faictes par la pouldre à non." Paris, 1545.

"In the year of our Lord 1536 Francis, King of France, who his distinguished actions and deeds in War and Peace was named 'the Great,' sent a powerful army over the Alps . . . rtly to provide Turin with provisions, troops, and other cessaries and partly to recover the towns of this province ich had been captured by the Count Guasto [Vasto] in mmand of Imperial troops. I found myself then with the yal Army as Surgeon attached to the infantry under the preme command of Montejan. The Imperialists had seized e Pass of Susa, the Camp of Villa, and had occupied all other proaches, so that it was only by great force that they could driven out of those positions and the Royal Army had to en the way for itself with the sword. In this concourse and such a conflict of armed men there were a large number unded by shot of both sorts,[4] but specially those caused by illery. I must, however, admit that at that time I had not rdened my spirit too much with the knowledge of surgery d especially was not yet very learned in the treatment of uries caused by artillery. I had, it is true, read in Joh. gonius that wounds caused by firearms were poisoned by ason of the gunpowder. One must, therefore, in order to heal em burn them with boiling oil of elder (Sambucus) mixed with mall quantity of Theriak.[5] As, however, I had not too much th either in the author or his remedy, and as I certainly was are that it was impossible to use burning expedients in relation wounds without causing the most fearful pains and worries, lesired before taking the risk myself to observe and to satisfy rself by my own eyes whether the other surgeons who were in e same camp with me made use of any other treatment of unds. I perceived, however, that they all observed the ethods prescribed by Vigonius and endeavoured as soon as ssible to introduce boiling oil into the wounds by means of a nt. This encouraged me to attempt the same with those ses which were entrusted to me. It so happened, however, at by reason of the great numbers of wounded who came in at my supply of that oil ran out. As there were still several ses calling for treatment I saw that, if I was not to pear to have done nothing and to be leaving them in e lurch without any treatment, I must lay on a so-called igestive remedy' consisting of yolk of egg, oil of roses, and rpentine. Having done so I passed a sleepless night, for I was depressed and worried about the treatment of the previous day, as I thought it was of no avail. I feared that when on the following day I came to remove the bandages I should find the wounded men either dead or dying in consequence of the poisoned wounds, as I had not cauterised them with the boiling oil. Therefore, I rose very early, visited the sick and observed, quite contrary to my expectation, that those whom I had treated with the digestivum had passed the whole night without serious pain and that neither inflammation or swelling manifested themselves in their wounds; on the other hand, that those I had treated with the boiling oil were in a fever with terrible sufferings and swellings round the wounds. Having subsequently several times had the same experience with many other cases, I came to the resolution never again to treat cases of gunshot wounds with boiling oil."

Little can be added to these words. They demonstrate clearly that Paré, fully recognising the uselessness, indeed the folly of the treatment of gunshot wounds then in vogue, had gone over to, or more accurately speaking had returned, as we should say to-day, to a more conservative treatment. For his expedients coincide in principle and in many details with those which in ancient medicine were adopted by Hippocrates and the medical men who followed him. With respect to the most important principles Paré clearly says, "que pour bien estraire les balles demeurées dedans quelque partie du corps, il falloit situer le blessé en telle situation, qu'il estoit, lorsqu'il fut frappé." Moreover, cases are to be treated by the use in the first instance of cleansing methods, but not the oil (les médicamenter au usant de suppuratifs au commencement, et non d'huile bouillante).[6] Furthermore, he says in support of his view, that gunpowder cannot possibly be poisonous; for in the first place its constituent parts were not of that nature; moreover, that soldiers frequently used it internally as a sort of antidote and went so far as to rub it into sores in order to dry them up. Another widely accepted opinion he also shows to be erroneous—namely, that the balls become so heated from being fired that they burn the wounds which they cause. He says that this is absolutely untrue, "car une balle estant tirée contre une muraille, on la pouvoit promptement teniz en main nue, combien que pour la collision faite contre la pierre, elle devroit encore estre plus echauffée."

Removal of the Missile.

In detail Paré gives the following directions [7] for treatment. After a short introduction on the varying sorts of gunshot wounds according to parts hit and injured as well as the symptoms produced, he gives advice as to first treatment (premier appareil). The wound, if the position of the body permits, is to be enlarged by an instrument, in order to remove dirt or foreign bodies which may have got into it. In order to ascertain the position of the missile the wounded man, as already mentioned, should be placed in the same position as that in which he was when he was hit, "pourceque les muscles et autres parties autrement situées peuvent estomper et empêcher la voye." Then an attempt is to be made to remove the missile with the finger. If this is unsuccessful, by reason of its being too deep-seated or for any other cause, a long probe with a thickened but rounded end is to be used.

The list of instruments for the extraction of balls is fairly long and very cleverly adapted to varieties of projectiles and the wounds caused by them respectively. As regards the former he mentions, amongst guns: bom cardes, canons, doubles-canons, bastards, mosquets, passe-volans, piéces de campagne, couleuvrines, serpentines, basilisques, faucons, fleutes and many others; amongst hand firearms: pistoles, pistolets, petits bidets, petits lezards et scorpions, harquebuses à croc, mousquets and many others. In addition quite a number of explosive bodies which are not projected from a firearm are mentioned, such as mines, sapes, pots à feu, and grenades, &c.

That these very various missiles, which both in their form and effect produced wounds very different from the earlier weapons which Paré himself designates as children's toys, required not a few tools to deal with them is obvious, and we find quite a number of such: toothed tongs in the shape of crows' beaks (bec de corbin dentelé), the lizard's snout (bec de lézard) and many another toothed implement. The "ball extractor" (tirefond) which had a sharp boring tool that turned within a long straight tube served the special purpose of screwing into leaden bullets which were set fast in the depth of the wound and so to extract them. For the widening of the passage of the missile, as well as knives, there were special "dilatatoires," consisting of several arms which could be spread out, like the "specula" used already in ancient days.

Cleansing the Wound.

The general condition of the patient was not lost sight of after the missile had been extracted, and directions as to diet and bleeding were given. If the wound is dirty and

shows no sign of cleansing itself (pourriture) he seeks to bring it about by methods similar to those of the surgeons before his time. In these puppy oil (oleum catellorum) plays a great part. It was made by boiling quite young puppies in oil till they were entirely dissolved, with the addition of earthworms, turpentine, and spirits of wine, and was intended mainly to bring about a mild suppuration. If, however, there are signs of decomposition at the start he combats them by remedial measures (remèdes contrariants à la putrefaction). The chief remedy for this purpose is "Egyptiac" consisting of alum, verdigris, and Roman vitriol boiled into a thick syrup with honey and vinegar. This was introduced into wounds by probes or tents or injected by means of a long syringe. Later on Paré used in place of these instruments metal drainage tubes made of gold, silver, or lead (pourtant j'approuve d'avantage les tentes cannulées, faits d'or, d'argent ou de plomb). Compresses with holes made in them are then laid over the wounds, so as to allow of excretion from the wound to run away; these in their turn are covered with an absorbent sponge, and the whole fixed by bandages. The dressing must be renewed every 24 hours until the wound begins to suppurate, and after that every 12 hours, and in the case of severe suppuration at still shorter periods. When the wound has cleansed itself, mollifying and soothing remedies were used for the after-treatment.

Amputations.

There is no doubt that Paré by these improvements in the treatment of wounds did a great service; not only were innumerable wounded men saved from incurable sickness and from death, but his methods also led to the reform of other branches of surgery, a large number of hitherto faulty methods being perfected. For the military surgeons the chief questions for consideration were his improvements as regards amputation and styptics as well as his directions regarding substitutes for lost limbs (prosthesis) and orthopædic apparatus. With the words, "L'art commande que l'on commence à la partie saine," [8] that is to say, that in cases of amputation a surgeon must always work in sound tissues, and not in the diseased parts, but above them, he sets up an axiom at variance with that of the ancients which to us nowadays is self-understood, but at that time involved a great advance. He very properly, however, limits his laws by directing that the surgeon must always seek to preserve as much as possible of what has remained sound. Paré also considerably improved the methods of carrying out an amputation. The problem of restraining hæmorrhage, which from earliest times was a difficult one, was in his day universally solved by cauterising with a red-hot iron the blood-vessels which were severed in the course of amputating a limb. Even whilst the desired result was achieved in most cases, the severe burning of the tissues produced conditions which were not exactly conducive to a rapid and even healing of the wound, and in which several dangers lay hidden. "Il faut promptement lier les grosses veines et artères si ferme qu'elles ne fluent plus," says Paré,[9] thereby reintroducing the method practised by the ancients, but long entirely forgotten, of tying the arteries. Even if his technique seems still very rough, yet it fulfilled its purpose to such a degree that at one fell swoop it did away with a great part of the dangers of an amputation. And, reviewing the matter, he speaks of the immediately preceding method as "chose très horrible et cruelle seulement à raconter: car cela causait une extrême douleur aux patiens," and, moreover, scarcely one-third of the number so treated escaped with their lives.[10]

Artificial Limbs and Appliances.

Paré dedicates a whole book [11] to the substitutes for lost limbs (moyens et artifices d'adjouster ce qui défaut naturallement ou par accident). Whilst as regards the treatment of plastic operations, that is to say, substitution by living parts, he displays no advance upon his predecessors, but on the contrary on many points, such as his description of plastic treatment of the nose, he is in error, yet he shows himself fully equal to many other tasks. For instance, as regards defects of the palate, arising from shot wounds or other violence, and which may affect the powers of speech seriously, he suggests contrivances which he designates as "obturateurs du palais." They are cleverly affixed to the palate and so entirely cover the orifice that a normal function is again restored.[12] So, too, for ears that have been cut off and for other parts he provides an artificial substitute.[13] Difficult problems such as compensating the loss of power to move a thumb, the extensor muscles of which have been severed, he solves by the application of an appropriate artificial part to the wrist which replaces the power to move the thumb, so that the limb can again be used to hold a sword.[14] By the coöperation of a clever locksmith and mechanic he also was enabled to give descriptions and drawings in his works [15] of artificial hands, arms, and legs, which enabled any capable workman to produce artificial parts in accordance therewith. Thus, he constructed an artificial hand which, by a very ingenious but somewhat complicated mechanism, afforded a certain amount of movement actuated by the muscles of the arm on which it was fixed in a peculiar manner. The same applies in greater degree to an artificial arm which he invented. One of these was probably worn amongst others, by a Huguenot captain who had lost his arm by a gunshot wound at the Siege of Fontenoy. The apparatus is alleged to have worked so well that he was enabled thereby again to handle the reins.[16]

With all the above we have by no means exhausted Paré's services in the field of surgery. Rather does one see his improving hand in many details of the treatment of wounds in the days that came after him. And wherever his activity becomes apparent Paré proves himself not only a surgeon in the narrower sense of the word, that is to say, a man who looks upon his profession as manual labour, but as a true doctor; who, in act and deed, follows the maxims which he himself has set forth in verse in his "Canons et règles," [17] and of which one reads:

Science sans experience
N'apporte pas grande assurance.

A SYMPATHETIC PSYCHONEUROSIS.

To the Editor of THE LANCET.

SIR,—It may interest your lay correspondent that Mrs. Leather, in her "Folk-Lore of Herefordshire," states that in that county it is quite generally believed that the father frequently suffers as much or more than the mother of his first baby, and sometimes, but more rarely, at the time of subsequent births. The pain may even be transferred to the husband altogether and any tooth, or other ache, affecting the husband at this time is ascribed to the same cause. Mrs. Leather (p. 111) gives three examples. She also reproduces the explanation of an old woman at Garway: "I allus thought as the Almighty appinted that very wi, so the poor woman 'ad ha' more strength when the time came." Mrs. Leather suggests that the superstition is the last trace of the *couvade* custom.

I am, Sir, yours faithfully,
MACLEOD YEARSLEY
Wimpole-street, W., April 16th, 1928.

CENTENARY OF THE INVENTION OF COCOA.

A HUNDRED years ago, in April, 1828, a Dutch chocolate manufacturer, Coenraad Johannes van Houten, discovered a process whereby cocoa-powder as it is known to-day could be made. The cocoa-bean had already been introduced into Europe from Mexico by General Cortes 200 years before this, but until van Houten made his discovery, the cocoa and chocolate industry had remained an insignificant affair, and the housewife who wished to make the beverage was reduced to boiling rock chocolate for a lengthy period. During the whole of this week celebrations are being held in the little Dutch town of Weesp, near Amsterdam, by the members of the family of the inventor, who still control the business, to commemorate the centenary of the beverage they manufacture.

THE DOCTOR'S EMERGENCY REMINDER.

WE have received from Messrs. J. C. Eno, Ltd., a tastefully leather-bound little book of a size to fit the waistcoat pocket which contains useful notes on the stocking of an emergency bag, and hints on dealing with poison cases, hæmorrhage, shock, anæsthetic emergencies, and drowning. The commoner poisons are arranged alphabetically with a summary of symptoms and treatment. Members of the medical profession can obtain the book free on application to the Messrs. J. C. Eno, Ltd., Lever House, Victoria Embankment, London, E.C.

THE Crookes Laboratories, London (British Collosol, Limited), are now represented in America by their associated house—British Colloids Company, 145, East 57th-street, New York—from which Collosol products can be obtained direct.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—The annual conversazione of this Society will be held at the Kensington Town Hall, on Friday, June 15th, at 8 P.M. At 8.30 the Cavendish Lecture will be given by Dr. A. Rollier, of Leysin. His subject will be The Therapeutic, Preventive, and Social Value of Heliotherapy in Surgical Tuberculosis.

An Address

ON

RADIUM IN THE TREATMENT OF MALIGNANT DISEASE.

Delivered for the British Empire Cancer Campaign and Yorkshire Post-Graduate Association at Leeds on April 4th

By G. E. GASK, C.M.G., D.S.O., F.R.C.S. Eng.,
SURGEON AND DIRECTOR OF THE SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL; PROFESSOR OF SURGERY IN THE UNIVERSITY OF LONDON.

Although radium has been known for 30 years, and employed as a remedial measure in all sorts of disease, the results have, on the whole, been disappointing. Hope has been kept alive by occasional inexplicable cures, but these have been so few that practitioners have been led to believe that radium was not a therapeutic measure with which they need trouble themselves much, and that as regards malignant disease it was to be kept for use in those instances of inoperable growths for which nothing else was available. Events which have taken place during the last few years are, however, altering our conception of the value of radium and making it desirable that clinicians should reconsider their opinion, carefully examine present knowledge, and keep a watchful eye on future developments. The reason for this change of attitude is the result of recent work and development in the technique of handling radium and of applying it to the treatment of malignant disease. It can now be stated that it has been proved indubitably that in a considerable number of cases undoubted malignant tumours have been observed to disappear after exposure to the rays of radium.

The object of this address is to give a brief statement of the present position of the use of radium in malignant disease and to set out, as fairly and honestly as possible, the judgment of a surgeon who has had the opportunity of observing and assessing the value of some of the recent work done.

Summary of the Physical Properties of Radium.

In 1895 Wilhelm von Röntgen discovered the rays which are now known as the Rontgen or X rays. Other radio-active substances were discovered shortly afterwards, and in 1898 Prof. and Mme. Curie isolated two radio-active bodies from pitchblende and called them radium and polonium. Radium is found in nature in small quantities in certain mineral deposits, of which the richest are in the Belgian Congo. It is a lengthy and costly process to extract the radium from these deposits, and to give some idea of the difficulty involved it has been stated that from one ton of ore only half a gramme of radium is obtained. This lengthy and intricate method of production is given as the reason for the very high price. One gramme of radium (a threepenny-piece weighs about a gramme) costs approximately £11,000 at the present time. Radium in its metallic state is a pure white metal, which changes quickly when exposed to air and reacts with water. Therefore for therapeutic measures it is always prepared and used in the form of salts, generally as radium bromide. The most important radio-active elements are uranium, radium, polonium, actinium, and thorium. Radium is by far the most important, because it disintegrates at a convenient rate, which allows the use of its radiation over a long period.

Radio-activity is defined as the spontaneous emission of certain atoms or rays. This emission is the outward evidence of the spontaneous disintegration of the radio-active substance, atom by atom, into other substances. One per cent. of a radium mass disintegrates in each 25 years. Therefore the radio-activity of a pure radium preparation continues for an average life of 2500 years. The final product of radium after disintegration is lead.

Each of the radio-active substances is formed from the one preceding it after an outburst of energy, evidenced by the emission of rays. The rays emitted by radium are of three varieties, known as alpha, beta, and gamma rays. The property of these rays is threefold: (1) they act on photographic plates; (2) they cause certain substances to fluoresce; (3) they have an ionising influence. It is with the ionising rays that we are most concerned in the treatment of malignant disease, because they have a distinct effect on living tissue.

Effect of Irradiation on Animal and Vegetable Tissues.

A very large number of experiments have been carried out in order to ascertain the effect of the action of radium on living tissue, both animal and vegetable. The results of these experiments, which have been detailed at length by Colwell and Russ, may be summarised briefly by saying that in certain doses animal life is adversely affected. Destruction of tissue occurs, the growth of embryos is checked or altered, and prolonged irradiation may cause death. The effect on vegetable life is similar; growth is interfered with, and alteration occurs in structure. Experiments on bacteria indicate that the rays of radium are capable of arresting and, if sufficiently intense, of stopping the growth of cultures. The bactericidal power of radium is sufficient to kill cultures of organisms such as *Bacillus coli communis*, *Staphylococcus aureus*, and *Bacillus pyocyaneus* in a comparatively short time. The effect of the rays on living tissue appears to be a local one. It is evidenced by alterations of shape and activity of the nucleus, and when irradiation is sufficiently powerful or long-continued the cell dies. Some forms of tissue are more easily affected by irradiation than others, and tissues in active growth are more vulnerable than fully formed tissues. Cells of the ovary and testis are more easily killed than fully formed fibrous tissue cells. Tissues in which cell division is most active are the most vulnerable of all. It is well known that mitosis is very active in cancer cells, and thus it is possible to expose neoplasms to the rays of radium and to kill or injure these cells without killing the other cells of the body.

Radium as a Therapeutic Agent.

The use of radium as a therapeutic agent was discovered by accident. The French physicist, Becquerel, it is stated, put some tubes containing radium in his pocket and carried them about with him for some days. He found that the radium had burnt his skin. So he discovered that radium is capable of producing an inflammatory and, if continued long enough, a destructive effect on the normal skin—effects that are similar to the now well-known burns which may follow the incautious use of X rays. This phenomenon suggested to a man of fertile imagination—it has been stated that the man was Besnier—that the rays might be utilised to kill certain cells which are considered harmful to man. Then followed pioneer work by a number of people to whom reference cannot be made here. It was found quite early that radium had a beneficial effect on certain skin lesions, notably on rodent ulcer, and these ulcers were shown to disappear permanently after exposure to the rays. Gradually the use of radium was extended to the treatment of all sorts of diseases. Reports on these results were most confusing, and it was almost impossible for the ordinary man to assess their value. For the most part accurate details of the exact nature of the disease treated, the method of application, and the dosage were lacking. Clinicians therefore felt that its value as a remedial measure was too uncertain for them to recommend it to their patients, and its use fell into disrepute.

In view of these unsatisfactory and conflicting reports the Medical Research Council determined to institute an investigation which should be carried out

in a scientific manner on a large scale, so that reliable knowledge might be accumulated and distributed. At the close of the war a stock of radium bromide which had been collected in this country for military purposes was entrusted by His Majesty's Government for a period of years to the Medical Research Council. This stock was distributed among a number of research centres with a view to an extended and coördinated inquiry into the medical uses of radium, with especial reference to its application in the treatment of malignant disease. Subsequently further supplies of radium were provided by the British Empire Cancer Campaign, with the object of increasing the scope of the work, and an arrangement was made by which the Radiology Committee originally appointed by the Medical Research Council should also serve the radiological interests of the Campaign. The wisdom and foresight of those who initiated this research are amply justified, for reports from these centres are showing that substantial progress has been made and that remarkably beneficial results have been obtained from the use of radium in malignant disease.

Methods of Using Radium.

Since the application of radium in the treatment of new growths depends on subjecting the tumour to the rays, it is obviously necessary to bring the radium into such a position that the rays will fall on the

Fig 1.

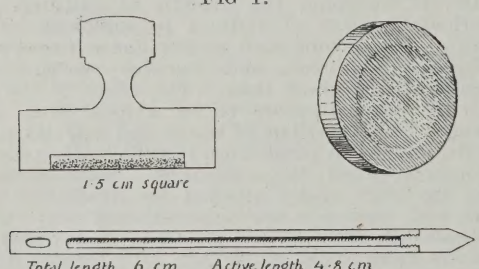

Diagram of surface applicators and section of a radium needle.

desired spot. The effective range of the rays of radium, with the quantity of the element at our disposal, is only about one centimetre, so that access must be gained to internal growths by one means or another—possibly by surgical operation. This constitutes what is known as "the surgery of access."

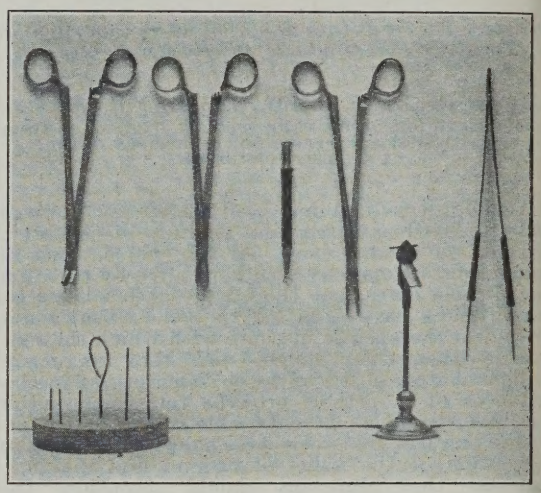
Surface Applicators.—Little difficulty is experienced with surface tumours, for radium salt, placed in a suitable container, may be applied to the desired spot and secured in position by adhesive strapping or a similar mechanical device. (Fig. 1.)

Radium Needles.—Surface applicators are obviously of little value for internal growths, such as tumours of the uterus, breast, or rectum. In such conditions use may be made of radium needles, the introduction of which marks a decided step in the evolution of radium therapy. The needle consists of a sealed glass tube in which is placed the required amount of radium, the tube is inserted into a container made of some metal, such as platinum, silver, or aluminium. By varying the composition and thickness of this metal container it is possible to cut out or screen rays that are not desired. These needles may be inserted in or around the tumour so that the rays may fall on the required spot. The dosage given may be varied by the amount of the radium in the needles, the thickness and composition of the screen, and the length of time the needles are left in position. (Fig. 2.)

Radium Emanation.—Instead of using the radium element itself for the purpose of irradiation it is possible to draw off from it the gas it yields which is known as radium emanation, or radon, and also has radio-active properties, and can be used for treatment.

Radon is obtained directly from radium by dissolving it in dilute hydrochloric acid and connecting the containing vessel with an ordinary mercury pump. The emanation, as it is formed, may then be collected over mercury and sealed in capillary glass tubes. After a solution of radium salt has been "pumped off" in this manner, it begins immediately to "grow" more emanation which, after a certain time, may be

Fig 2.



Radium needles with introducers.

pumped off again. One might suppose that the original stock of radium would soon become exhausted but the wonderful thing about it is that it wastes extraordinarily slowly. The rate is so slow that the radium may be considered inexhaustible. According

Table showing Rate of Decay of Radium Emanation.

Time.	Radio-activity remaining per cent.	Time.	Radio-activity remaining per cent.
12 hours	91·393	5 days	40·657
24 ,, ...	83·527	8 ,, ...	23·693
2 days	69·768	10 ,, ...	16·530
3 ,, ...	58·275	20 ,, ...	2·732
4 ,, ...	48·675	30 ,, ...	0·452

to Rutherford, if a gramme of radium were isolated i would take 1690 years for one-half of it to be trans formed into the emanation. Radon has marke radio-active properties but decays very rapidly; thu in four days it has lost more than half of its initia activity, and at the end of 30 days is practically inert. (See table.)

Fig 3.

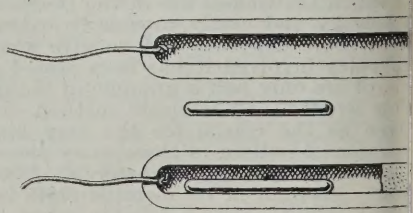


Diagram of a radon seed.

There are advantages and disadvantages in the use of the emanation rather than the element. One advantage is that the danger of loss of the costly radium, either by theft or acciden is reduced to a minimum, as the stock remains in th safe. Another advantage is that radium emanatio may be concentrated in capillary tubes and readil distributed in containers of any shape or size (Fig. 3 and these capillary tubes may be buried in the body an left in situ. A disadvantage is that the tubes con taining the emanation have a comparatively short lif owing to the rapid disintegration of the emanation.

Recently Dr. J. Muir, of New York, has introduce a very valuable method of using radium emanatio

This consists of a trocar and cannula (Fig. 4) which may be plunged into the tissues to the required depth; the trocar is then withdrawn, a radon seed introduced into the breech and pressed down into the tissue by means of the plunger. A fine thread attached to the seed allows it to be withdrawn after the requisite number of days. This method opens up a promising line of work.

Recent Work on the Medical Use of Radium.

Summaries of reports from research centres on the medical use of radium have been published by the Medical Research Council during the last

Fig. 4.

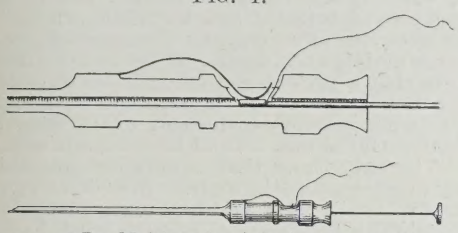

Diagram of Dr. Muir's radon introducer. (Approximate length 17·8 cm.)

few years and reveal substantial progress. It is well known that radium has been used successfully for a number of years in the treatment of rodent ulcers and of tumours on the surface of the body. Recently attempts have been made in various research centres to treat cancer in the deeper parts of the body, and special attention has been given to cancer of the uterus, breast, upper air passages, tongue, and rectum. Most of the remarks in this paper are based on personal observations made at one of these centres, but the writer is fully aware that much excellent work has been done elsewhere and in other countries.

In reporting on results it is particularly desirable to avoid false impressions, either good or bad, and especially to refrain from sensational claims of wholesale cures which might raise false hopes. Reference, therefore, will be made rather to the disappearance of the signs and symptoms of disease than to the cure of patients, which can only be ascertained definitely after the lapse of years.

Carcinoma of the Cervix Uteri.

It became obvious at a comparatively early date that carcinoma of the cervix uteri is amenable to treatment by radium and some very remarkable and brilliant results have been obtained. The technique which has been followed and found successful has been burying radium needles in and around the tumour with a space of approximately ½ cm. of tissue between each needle. These needles have been allowed to remain in position for about 144 hours and then removed. In all cases a portion of the growth has been excised for histological purposes, so as to make sure that the patient was really suffering from malignant disease. It has been alleged that it is wrong to remove a portion of the growth because of the danger of disseminating the disease. We have not found this objection borne out in practice, and it was felt essential for the purpose of the research to have accurate histological records. The immediate effect of burying radium needles in the patient is nil. There is no feeling of warmth or pain or discomfort, other than may be excited by foreign bodies in the tissues. The benefits, if they occur, are to be expected in the course of a few weeks. In many instances the tumour formation, which was obvious before irradiation, disappeared, ulceration healed, and hæmorrhage—a prominent and distressing symptom of the disease—ceased.

The report of one centre states that of 146 cases of carcinoma of the uterus in which hæmorrhage was present before irradiation, all hæmorrhage ceased in 124—that is, in 84·9 per cent.—though in some of these it returned later. Out of 69 patients in whom a tumour formation was noted before irradiation, it disappeared completely in 60. In a series of 92 cases in which the carcinoma was of the ulcerative rather than the proliferative type, the ulceration disappeared either temporarily or permanently in 62. It is not to be inferred that all these people were cured, for some of them died of metastases in various parts of the body. Many of the patients were the subjects of advanced disease, people who were considered unfit for any surgical operation, and many of them no doubt had at the time secondary deposits which were out of the range of the action of the radium. It has, however, in my opinion, been definitely proved that the action of radium will, in many cases, cause a primary carcinoma of the cervix to disappear (Fig. 5),

Fig. 5.

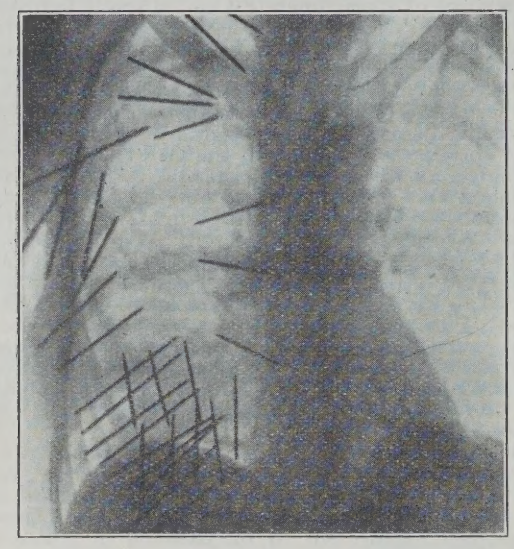
B = Histological preparation of the same growth, removed four weeks after irradiation, showing granulating tissue only. (×80).
C = Histological preparation of a portion of the same cervix uteri, 13 weeks after irradiation, showing much fibrosis and no growth. (×400.)

and bring about a cessation or diminution of the symptoms. It remains yet to be proved whether the patients so treated will remain free of disease, and for how long. It remains also to be proved, in the course of time, whether the operable patients will live longer

FIG. 6.



Radiogram from a patient with carcinoma of the breast, showing radium needles in position and barrage effects between breast and chest wall in the axilla, intra- and supra-clavicular and intercostal spaces.

if treated with radium or if submitted to surgical removal of the whole uterus.

Carcinoma of the Breast.

In the beginning of the research on carcinoma of the breast, the patients selected were those considered unfit for surgical operation on account of the widespread characters of the growth. It was soon found that, though the patients were in no sense cured, yet the action of radium on the primary tumour was marked and resulted in a definite shrinkage. Gradually a technique was evolved by which the action of radium could be made effective over a large area. This was obtained by burying needles underneath the breast between it and the chest wall, forming, as it were, a radium barrage. (Figs. 6, 7 and 8.) At the same time it was found possible to irradiate the glands in the axillary, supraclavicular, and parasternal regions. It was found also that, generally speaking, better results were obtained when the tumour was subjected to small doses of radium over a long period than to a large dose for a short time. The results so far have been most encouraging, though a great deal more work is required before any definite statement can be made.

Of a series of 13 patients who have been carefully observed, four have died of metastases in remote parts of the body, though all showed a shrinkage of the primary tumour. In the other nine the results have been very good; their tumours have disappeared and they remain in good health. They have not had mutilating operations, and they are very pleased with the results. It is not held that they are cured of their disease, but they are free of the signs and symptoms. Moreover, the results are good enough to justify the treatment of more patients in the same manner, and the choice of patients who are not in the advanced stages of the disease and who would be, in the general sense, fit subjects for surgical operation.

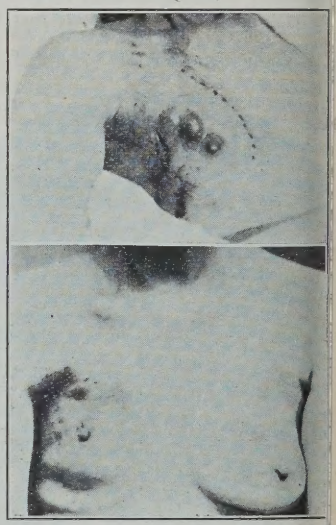
Carcinoma of the Upper Air Passages.

The difficulties of dealing surgically with tumours of the pharynx and larynx, and the extensive and mutilating operations which have been devised for their removal, are well known to surgeons. In radium we seem to have a method which may supplant these old operations. The report from one of the research centres is to the effect that in early cases, in which the disease is strictly limited, disappearance of the tumour and relief of all symptoms can be expected in a high percentage of cases. The after-results are also far superior to those which have been obtained from operation, for in many instances the vocal cords may become normal and the voice be restored.

Carcinoma of the Tongue.

Surgical treatment of carcinoma of the tongue and of the floor of the mouth has never given satisfactory results, whereas the effect of radium has in many instances proved brilliant and surprising, in that the primary growths have entirely disappeared, leaving the tongue mobile and intact. It seems very difficult to believe that a proved epitheliomatous ulcer of the tongue will disappear, that the skin will heal, and the tongue become mobile at the end of 17 days after treatment with radium. Yet I have myself seen that occur. The only thing that is at all comparable to it, in my experience, is the manner in which a gummatous ulcer will melt away and heal under the influence of antisyphilitic treatment. Enough work has been done on carcinoma of the tongue to show that in many instances the primary growth has disappeared completely, that the function and mobility of the tongue is almost unimpaired, and that the patient remains free from the primary growth at any rate for a number of months. This, of course, does not mean that the patient is cured, because of the possibility of dissemination into the lymphatic glands of the neck and into the lungs. The treatment of the lymphatic area remains a difficulty which has yet to be overcome, and it is possible that the right treatment may be to irradiate the primary growth in the tongue and to remove the lymphatic glands in the neck by block dissection. A great deal more work is required in this direction.

FIG. 7.



Photograph of a patient with advanced carcinoma of the breast immediately after insertion of radium needles. Punctures show where the needles were inserted. The lower half of the picture shows the same patient one year and eight months after. It will be seen that the tumour has disappeared.

Carcinoma of the Rectum.

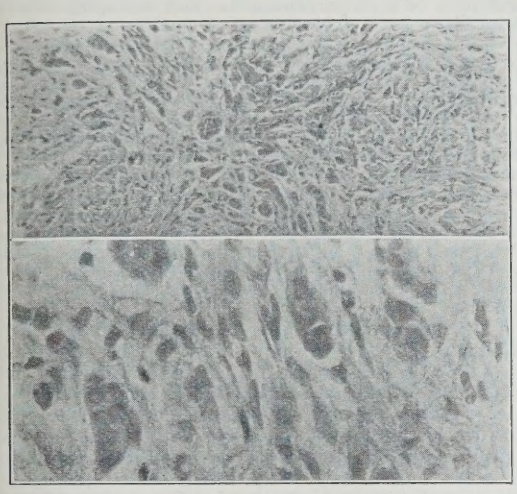
From work on the subject of carcinoma of the rectum it would appear that insertion of tubes containing radium into the lumen of the bowel is not sufficient to destroy the growth, owing to the limited range of the rays. Investigations are proceeding now with the object of obtaining access to a carcinoma of the rectum from the outside by a surgical operation, so that radium needles may be inserted about the periphery of the tumour. A report from one centre states that 15 cases of carcinoma of the rectum have been treated by radium barrage after open operation. The results show that in both operable and non-operable cases the primary growth can be destroyed, but that there is no evidence at present to show whether the spread of the disease into the lymphatics

and distant parts can be checked. These results certainly justify further attempts.

As an instance of the use of radium emanation in the treatment of malignant growths in the deeper parts of the body, the following case may be cited :—

A patient, aged 35, suffering from malignant new growth of the testis with secondary deposits in the lymphatic glands on the left side of the aorta, had his testicle removed by operation. The abdomen was opened, and 11 radon

FIG. 8.



Histological preparation from portion of tumour showing spheroidal-celled carcinoma. (× 70, × 440.)

seeds with a strength of 4·1 millicuries were introduced into the mass of glands and left there. Three weeks later the lump was obviously smaller, and after nine weeks it was hardly palpable. The patient remains well, and has put on 9 lb. in weight.

Conclusions.

The conclusion from these observations is that radium has a very definite action on malignant tumours, causing their disappearance. It would not be right at the present time to state that patients are cured, because it is difficult to state any period after which it is certain that there will be no recurrence. Sufficient has been said, however, to show that some patients have been freed from signs and symptoms of disease and have remained free for many months, without the extensive and formidable operations which are so distressing both to patients and to surgeons. I myself have been for some years in the position of an agnostic, not convinced of the benefits resulting from radium in the treatment of malignant disease, but watching its developments closely. I am now convinced that we have in radium a means of treating cancer which will prove of inestimable benefit.

A few weeks ago Mr. Hayward Pinch, the Director of the Radium Institute in London, gave an address at the Royal Society of Medicine in which he made the following prophecy, which he allows me to quote :—

"I make this statement deliberately and after the fullest consideration. I believe that in the very near future radium will form as important a part of the up-to-date surgeon's equipment as his scalpel, and he will be able to treat with confidence and success many cases of malignant disease which are at present regarded as inoperable and hopeless."

It is my deliberate opinion that he will be justified in his prophecy. It must, however, be fully realised that we are only on the threshold of the subject and that a vast amount of work is still required, involving the coöperation of physicists, chemists, physiologists, pathologists, and clinicians.

One of the things that hamper the work is the limited supply of radium, which is so expensive at the present time. If the advantages of the use of radium come to be realised by the medical profession and by the public at large it should not be difficult to increase the stock in this country. One of the functions of the British Empire Cancer Campaign might be to increase that stock, and even to go further and raise a fund for the foundation and endowment of a great national institution in which a large series of cases of malignant disease could be treated and the physical properties of radium observed.

THE TREATMENT OF PERNICIOUS ANÆMIA WITH LIVER AND LIVER EXTRACTS.

BY STANLEY DAVIDSON, B.A. CAMB., M.D., F.R.C.P.EDIN.,
ASSISTANT PHYSICIAN TO LEITH HOSPITAL;
J. G. McCRIE, M.B., CH.B. EDIN.,
STARK SCHOLAR IN CLINICAL MEDICINE;
AND
G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P. EDIN.,
PROFESSOR OF MEDICINE AND CLINICAL MEDICINE IN THE UNIVERSITY OF EDINBURGH.

FOR the past two years the medical press in America has been commenting on the claims of Minot and Murphy [1] that a diet rich in liver produces remarkably beneficial results in the treatment of pernicious anæmia. It is only during the past year (and particularly since July, when a paper on the subject by the originators was read at the British Medical Association meeting in Edinburgh) that the profession in this country has realised the importance of this recent therapeutic advance. Minot and Murphy stated that, during the past three years, 125 cases of pernicious anæmia had been treated with a diet whose essential constituent consisted of 200 g. of liver per day, either raw or lightly cooked. They claimed that no case, which had taken liver regularly and in sufficient quantities, had ever relapsed, and that their blood counts had remained constantly between 4 and 5 millions. Such remarkable results have never previously been obtained by any method of treatment employed in the past. These claims have been substantiated by many workers in America and elsewhere. The present series is considerably larger, however, than any so far reported on in this country.[2 3 4] In addition, the results of treatment with several makes of liver extract are here given. Forty-two cases of pernicious anæmia have been treated with whole liver or liver extract. The blood counts of 28 of these, before and after treatment, are appended.

Credit must be given to Whipple and Robscheit-Robbins [5] for the original experimental observations on which the clinical trial of a high liver diet was based. These observers claimed that, in the treatment of experimental hæmorrhagic anæmias in dogs, a diet rich in liver exerted a remarkable regenerating effect. The clinical application of these observations has amply confirmed their claims.

A feature of pernicious anæmia which necessitates the acceptance of the value of any therapeutic remedy with great caution is the occurrence of natural remissions. A remission may occur, with or without treatment, at any period of the disease, and is subject to no known laws of onset, degree, or duration. Since the exhibition of liver produces an artificial remission which differs qualitatively in

no way from a natural remission, experimental proof of the specific action of a high liver diet is essential.

The evidence as to the beneficial action of liver is of two kinds. There is first the fact that no case of pernicious anæmia, treated by Minot and Murphy with a high liver diet, has failed to respond. Moreover, no case, having improved and continuing to take the treatment, has so far relapsed. It is certain that many of these cases during the past three years would have relapsed on any former method of treatment. So far, none of the cases quoted below has relapsed, but we are not prepared, until further time has passed, to make any definite assertions on this point. Secondly, there is the direct evidence of the regenerating effect of liver on the bone-marrow, as adduced from the presence of increased numbers of reticulocytes in the circulating blood. The same phenomenon occurs in a natural remission, but its constant production within narrow time limits from the onset of treatment may be taken as definite proof that the treatment is responsible for the production of the remission. With regard to this direct evidence, we are perfectly satisfied as to the specific action which liver exerts on blood formation.

Reticulation.

So important is the part played by "reticulocytes" in the production and clinical recognition of a remission that we propose briefly to review the phenomenon of "reticulation." For the demonstration of the phenomenon, vital staining—i.e., the treating of the blood with a suitable stain without any previous or concomitant fixation—is necessary. When a film stained in this way is examined under the microscope, reticulocytes are seen as erythrocytes containing a variable amount of stained material—sometimes in the form of a definite network, sometimes in the form of scattered granules or dots. The nature of the stained material is still doubtful, but it is usually taken as representing a cytoplasmic reticulum, and not as being a product of nuclear degeneration. However that may be, there appears to be no doubt that these reticulated cells are the relatively young cells in the circulation, the reticulum disappearing as the cells mature. The phenomenon is thus closely related to that of polychromasia, and to some extent also to that of punctate basophilia—all three of these probably representing "different morphological aspects of the same thing, the basophil substance of young erythrocytes," though the latter—i.e., punctate basophilia—is "an aspect seen only in pathological conditions; it is an indication of pathological alteration rather than of mere youth" (Gulland and Goodall [6]). A good account of the reticulated red cells (with excellent microphotographs) is given by Hawes,[7] in a paper on the results of the study of normal and infant blood, and of blood from cases of pernicious and other types of anæmia, due both to disease and to traumatic hæmorrhage. All his findings support the view that reticulocytes are normal young cells (and probably the same cells which show polychromasia when stained by the ordinary methods). Periods of clinically obvious blood regeneration were always found to be associated with an increased percentage of reticulocytes in the circulating blood. "In fact, all are agreed that the reticulated cells represent the young growing red cells. Why these cells are not seen in the ordinary fixed preparation, stained by ordinary means, is a mystery. Apparently these youngsters are differentiated only by the delicate method of vital staining" (Dameshek [8]). They are present in normal blood to the extent of 0·5 per cent. to 2 per cent. It is obvious that, if reticulation be "a criterion of youthfulness in circulating corpuscles" (Piney[9]), the proportion of reticulocytes in the circulating blood will be an excellent index of bone-marrow activity. We should expect that, in the case of pernicious anæmia, and taking the usual view of its pathology—namely, defective or perverted blood formation in the marrow—a period of improvement should be heralded by a rise, and a relapse by a fall, in the reticulocyte count. That this is so is well brought out by Dameshek [8]; and the reticulocyte rise during the first stage of a remission is shown in the cases quoted below.

Technique of Vital Staining.

Various methods are described in the papers quoted above, but the following methods have been found satisfactory: The dye used is brilliant cresyl blue, in 0·3 per cent. solution in absolute alcohol.

Fluid Preparations.—A drop of the dye is spread evenly over part of a clean glass slide, and the spirit allowed to evaporate; even drying is much facilitated by previously warming the slide. The thin film of dry dye is then polished by gently rubbing the slide, face down, on smooth paper. By means of another slide, a film of blood is spread in the ordinary way over the prepared part. A clean cover-slip is then immediately placed on the most suitable part of the film, and gently pressed down to ensure contact with the blood. This preparation keeps fluid for some hours. In it the reticulocytes are visible as cells containing network, granules, or dots, of blue-staining material, as above described. Several hundred red cells can be counted, and the number of reticulocytes seen during the process noted. The insertion of a suitable stop in the eyepiece facilitates counting. An oil-immersion lens is desirable, as slight degrees of "reticulation" are otherwise apt to escape notice.

This method of making the preparation is, in our experience, superior to that usually described—namely, taking a drop of blood on a cover-slip, which is then inverted on a prepared slide and gently pressed down. The cells are apt in this case, we have found, to run into clumps and rouleaux, and so render counting difficult. A source of error common to all such methods is that even distribution of the reticulocytes is not obtained. We have noted that these cells appear to have a greater tendency to stick to glass than have the mature cells, for, if the cover-glass of such a preparation be gently pressed upon, ordinary erythrocytes may be seen surging across the field in large numbers, passing the sluggish irregularly moving reticulocytes. Thus we may find aggregations of, say, 100 cells, with not a single reticulocyte among them, while in another part of the field there may be three or four reticulocytes in 30 or 40 cells. The errors in the percentage count due to uneven distribution of reticulocytes are greatly reduced by counting the numbers of reticulated cells present in widely separated fields; and, indeed, Dameshek [8] found "no material difference" in checking up this method of counting with the very accurate method (Luzzato and Ravenna) of making a "absolute" count in a Thoma-Zeiss chamber, the cover-glass of which has been lightly smeared with cresyl blue on its lower surface.

Permanent preparations can be made as follows. A cover-slip is charged with the dye and polished, as described above in the case of slides. A drop of blood is taken on a second clean cover-slip, which is then placed face downwards on the first, and the blood allowed to spread out between the two. After an interval of 30 to 60 seconds, the cover-slips are drawn apart and the films allowed to dry. They can then be stained with any of the usual blood stains, such as Jenner or Leishman, and mounted in the ordinary way. A significant point is that polychromasia and stippling are not seen in specimens so prepared, although a film of the same blood, stained with Jenner, &c., without previous vital staining, does show this phenomenon. This is further proof of the relation between reticulation, polychromasia, and stippling. These preparations have the advantage that they can be studied at leisure, but it is probable that counts made from them are less accurate than those obtained by the wet method described above, since some of the vital stain is washed out during subsequent procedures.

Clinical Significance of Reticulation.

The appearance of reticulocytes has already been described. They are red cells, within whose cytoplasm may be discerned blue staining material—either in the form of a definite network, or in the form of scattered threads and dots. The former are apparently the younger cells, and, as they mature, the reticulum undergoes intracellular disintegration and disappearance. Thus we have noted that, following liver therapy, the cells which first appear show

a well-marked reticulum, while during the period of decline the degree of reticulation becomes less and less until the great majority of reticulocytes present show only scattered dots of blue.

A further point requires to be noted. Reticulated cells are sometimes present in fair numbers in untreated cases of pernicious anæmia, which are nevertheless doing badly. It would appear, however, that these reticulocytes are abnormal, since Piney [9] (quoting Buckman and McNaugher) states that they can be differentiated from normal reticulocytes by their defective resistance to hypotonic saline solutions. It is also our impression that these cells are definitely larger than the reticulocytes which appear in the circulation during a remission. It is possible that they are "reticulated megalocytes" as opposed to "reticulated normocytes." This question still requires further investigation. It is, however, certain that the reticulocytosis occurring in association with a remission is quickly followed by a fall in colour-index, and also by a diminution in the average size of the corpuscles (as shown by measurement), so that the cells into which these reticulocytes mature are obviously smaller than was previously the case. It was, however, noted by Hawes [7] that even presumably "normal" reticulocytes—e.g., those appearing during regeneration after hæmorrhage—were invariably larger than normal erythrocytes, and this fact is well brought out in his microphotographs, suggesting that the physiological maturation of blood cells is accompanied by a diminution in size.

The significance of the phenomenon of reticulation has been dealt with at some length, because it is obvious that its recognition is essential in assessing the value of any given mode of therapy in pernicious anæmia. Remissions produced by treatment differ in no way from those occurring naturally. If, however, it is found that such a definite phenomenon as a marked rise in the reticulocyte count constantly occurs in such a definite period as five to ten days after the commencement of treatment, it is obvious that the possibility of coincidence is much reduced, and the claim of that particular mode of treatment to the term "specific" is strengthened. It is this aspect of the phenomenon of reticulation that appears to us to be of immediate interest.

Effects of Administering Liver.

In every case quoted below, the clinical symptoms and signs of pernicious anæmia were present. As these are so well recognised, it is, for the sake of brevity, not proposed to give the details of each case separately. The diagnostic points on which we lay particular stress are: (1) megalocytosis, with (2) high colour-index, (3) anisocytosis, (4) decreased platelets, (5) achlorhydria. In every case these five signs were present. The therapeutic results following liver treatment were also identical in every case. Again, for the sake of brevity, it is proposed to describe them in general terms only. From within 3 to 15 days from the onset of treatment, depending on the condition of the marrow, and the amount of whole liver given or the make of extract used, reticulated red cells appear in the circulation in increased numbers. By the time they reach their maximum the patient states that he feels better. The earliest visible sign of this well-being is seen as a slight rosiness of the skin covering the malar bones. After reaching their maximum the reticulocytes quickly diminish in numbers, but the rise in the red blood count and hæmoglobin percentage, which starts at the same time, continues. As the anæmia steadily disappears, all the classical signs associated with it likewise go. The blood picture in all its elements—red cells, white cells, and blood platelets—returns actually or practically to normal. Appetite returns; the patient puts on weight; and the gastro-intestinal symptoms improve. Symptoms referable to the nervous system, if of recent date, and of the nature of mild paræsthesias, may completely disappear. Where they are the result of actual nervous tissue destruction no cure can be expected, but further exacerbations do not occur (Minot and Murphy [10]). In short, within three or four months of starting treatment, the patient appears to have returned to normal health again. It should be noted that failure to continue the treatment results, sooner or later, in a relapse.

Treatment with Whole Liver.

The diet advocated by Minot might be summarised as being a well-balanced, ample diet, high in vitamins, low in fats and carbohydrates, and having as its essential daily component 200 g. of liver. No two cases require the same amount of liver for the specific effect to be produced. Amounts in excess of 200 g. may be necessary, or less may suffice. From practical experience, we are very strongly of opinion that unsatisfactory results are attributable to one fact alone, and that is the giving of insufficient quantities of liver. In several cases of the series quoted below, the patients were unable at first to take more than 4 oz. liver and 4 oz. liver juice per day. Rapid improvement was seen for the first six weeks, by which time the red count was approximately three millions. No further improvement could be produced until the amount of liver eaten was substantially increased. Some patients have a great abhorrence of liver, owing to its nauseating effect, and in these it is extremely difficult to bring the blood picture back to normal. It may be generally said that pernicious anæmia patients tolerate liver better than do normal persons, and we have invariably found that, as improvement continues, the dislike of the diet decreases. Some of the patients with counts of a million or below were so nearly moribund that the taking of solid food was an impossibility. Liver juice was tried, but this requires to be given in very large quantities before satisfactory results are obtained. In a personal communication to one of us (S. D.) Minot states that the giving of liver juice is the most unsatisfactory dietetic method, while raw pulped liver is the most efficacious.

During the last nine months of 1927, which corresponds roughly to the time when liver treatment was started in this country, one of us saw 27 cases of pernicious anæmia in private. Of these, 12 were in nursing homes or were so placed that the blood could be examined with fair frequency. Of these, 11 were treated with Minot's original diet, and their progress is shortly summarised below. The other was treated with Eli Lilly's liver extract and is included in the "extract" list.

CASE 1.—M. (male), aged 52. Third relapse. Nov. 2nd, 1927: R.B.C.'s (red blood cells), 3,060,000; Hb. (hæmoglobin), 63 per cent. Nov. 26th: R.B.C.'s, 3,680,000; Hb., 78 per cent. Has continued to improve since.

CASE 2.—M., 71. First attack. Oct. 10th, 1927: R.B.C.'s, 1,980,000; Hb., 48 per cent. Nov. 15th: R.B.C.'s, 4,520,000; Hb., 90 per cent. Has kept at same level since.

CASE 3.—M., 34. Old-standing pancreatic case; could never take arsenic. July 28th, 1927: R.B.C.'s, 3,190,000; Hb., 72 per cent. Oct. 26th: R.B.C.'s, 4,080,000; Hb., 80 per cent.

CASE 4.—M., 71. First attack. Oct. 11th, 1927: R.B.C.'s, 1,530,000; Hb., 42 per cent. Dec. 28th: R.B.C.'s, 4,100,000; Hb., 82 per cent.

CASE 5.—M., 55. Second relapse. July 9th, 1927: R.B.C.'s, 1,400,000; Hb., 35 per cent. Sept. 20th: R.B.C.'s, 4,000,000; Hb., 75 per cent. Has improved further since.

CASE 6.—F. (female), 63. Very chronic case; under observation for over 12 years. R.B.C.'s never got much above 3,000,000. Combined postero-lateral degeneration. Liver begun Oct. 4th, 1927: R.B.C.'s, 1,980,000; Hb., 46 per cent. Feb. 2nd, 1928: R.B.C.'s, 4,860,000; Hb., 90 per cent. Nervous symptoms much improved.

CASE 7.—M., 65. Very chronic case under observation for ten years. R.B.C.'s varying from 2,500,000 to 4,000,000. Liver begun Nov. 4th, 1927: R.B.C.'s, 2,170,000; Hb., 53 per cent. Nov. 18th: R.B.C.'s, 3,360,000; Hb., 70 per cent. Has done well since.

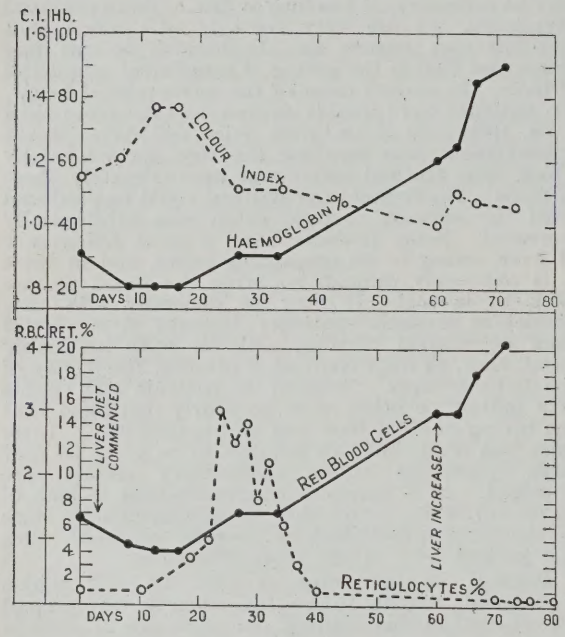
CASE 8.—F., 68. Chronic case of at least four years' duration. Marked postero-lateral degeneration of spastic

type. Liver begun Sept. 21st, 1927: R.B.C.'s, 3,120,000; Hb., 70 per cent. Dec. 16th: R.B.C.'s, 4,920,000; Hb., 90 per cent. Nervous symptoms worse.

CASE 9.—F., 28. Puerperal case. Liver begun October, 1927: R.B.C.'s, 2,400,000; Hb., 48 per cent. Dec. 17th: R.B.C.'s, 5,180,000; Hb., 80 per cent.

CASE 10.—M., 55. First attack but of chronic type. Marked weakness of arms, legs almost free. Liver begun July, 1927: R.B.C.'s, 3,260,000; Hb., 68 per cent. Feb. 4th, 1928: R.B.C.'s, 5,360,000; Hb., 100 per cent. Arms almost entirely recovered; legs completely.

FIG. 1 (Case 12).



CASE 11.—F., 40. Second relapse. Liver begun April, 1927: R.B.C.'s, 1,820,000; Hb., 50 per cent. Dec. 22nd: R.B.C.'s, 5,460,000; Hb., 85 per cent. Died of uræmia soon afterwards. Case was remarkable because there were throughout enormous numbers of nucleated R.B.C.'s, both megaloblasts and normoblasts, averaging about 11,000 per c.mm. and also a persistent polymorph leucocytosis from 15,000 to 19,000.

In addition, 16 other patients have been seen for diagnosis. Three of these died before the treatment was well started—one of cardiac failure, one of cerebral thrombosis or hæmorrhage, and one from uncontrollable vomiting, probably uræmic. The remainder are reported to be doing well on liver diet.

The following cases were under observation in the Royal Infirmary, Edinburgh:—

CASE 12.—M., 56. Third attack. (See Fig. 1.) Liver diet started on Nov. 14th, 1927, when the R.B.C.'s were at 1,340,000, and Hb. 30 per cent. Count continued to fall for some days, but by the eighteenth day reticulocytes had risen to 15 per cent., and blood thereafter continued to improve. Slow rate of progress, probably due to the fact that patient was unable to take full quantity of liver owing to teeth having been recently extracted. Commenced eating liver satisfactorily and regularly (6 oz. liver + 4 oz. liver juice per day) about Jan. 12th, 1928, since when, as will be seen, improvement has been much more rapid.

CASE 13.—M., 66. First (?) attack. Liver started Sept. 8th, 1927: R.B.C.'s, 2,600,000; Hb., 55 per cent. Oct. 10th: R.B.C.'s, 4,800,000; Hb., 64 per cent.

CASE 14.—M., 50. Third attack. Liver started Sept. 25th, 1927: R.B.C.'s, 1,850,000; Hb., 40 per cent. Nov. 17th: R.B.C.'s, 4,280,000; Hb., 70 per cent.

CASE 15.—M., 28. First attack. Liver started Sept. 9th, 1927: R.B.C.'s, 1,350,000; Hb., 34 per cent. Oct. 20th: R.B.C.'s, 4,890,000; Hb., 78 per cent.

CASE 16.—F., 39. First attack. Liver started August 8th, 1927: R.B.C.'s, 1,660,000; Hb., 35 per cent. Sept. 11th: R.B.C.'s, 3,270,000; Hb., 65 per cent.

CASE 17.—F., 58. First attack. Liver started May 2nd, 1927: R.B.C.'s, 2,000,000; Hb., 50 per cent. June 30th: R.B.C.'s, 4,130,000; Hb., 82 per cent.

CASE 18.—M., 66. First attack. Liver started Feb. 18th, 1927: R.B.C.'s, 1,720,000; Hb., 45 per cent. March 27th: R.B.C.'s, 2,960,000; Hb., 70 per cent. (Patient left hospital.)

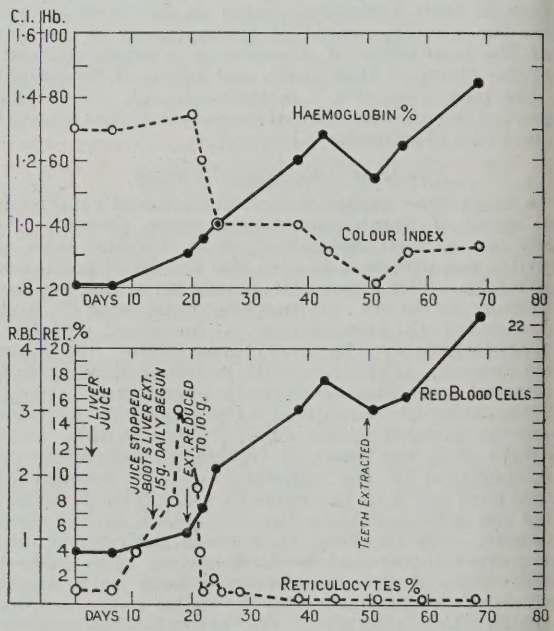
CASE 19.—M., 46. Second attack. Liver started Sept. 8th, 1927: R.B.C.'s, 2,670,000; Hb., 60 per cent. Nov. 7th: R.B.C.'s, 3,500,000; Hb., 60 per cent.

The importance of giving sufficient quantities of liver is clearly brought out in the blood counts of the earliest cases treated. They received what the writers now recognise to have been an insufficient quantity.

Treatment with Liver Extracts.

Cohn and his co-workers [11] have shown that, by a method of fractioning, a non-protein substance can be obtained, 5–15 g. of which is as efficacious as 200 g. of whole liver. As this substance is soluble in water, and exerts its action when given by the mouth, the treatment is greatly simplified for patients who are too ill to take solid substances, and is far more pleasant to those who object to the large amount of liver it is essential to eat. For these reasons, liver extracts will, in the future, largely supersede whole liver. Six different preparations have been tested, one being American, two being German, and the remaining three British. Since all these preparations were found to be active, the manufacturing process appears to present little difficulty. Their mode of action is identical with, but even more striking than treatment with whole liver, because it is possible to give the specific factor contained in 1000 g. of liver in one dose.

FIG. 2 (Case 20).



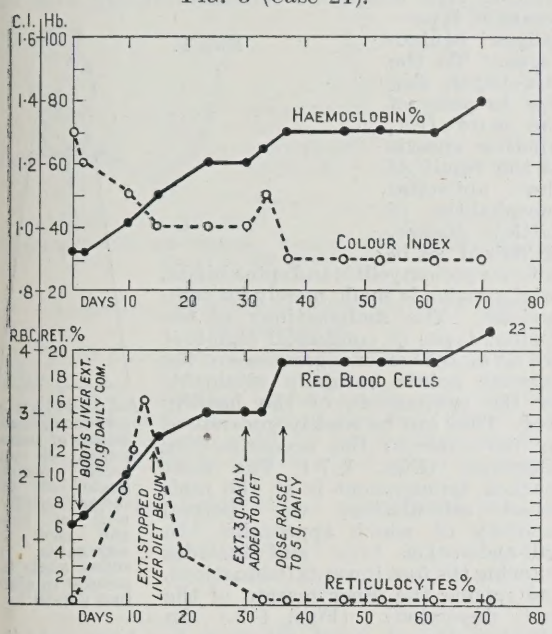
It is therefore unnecessary to recapitulate the history of the clinical improvement which follows their exhibition.

1. *Liver Extract Manufactured by Messrs. Boots.*—This product has received the most thorough trial of all the extracts, as one of us has been in touch with Dr. P. C. Brett, of Boots Pure Drug Co. since the inception of his researches. Four cases have been treated, either with the extract alone or in conjunction with whole liver. Fig. 2 shows its action when given alone; Fig. 3, when given with additional whole liver.

CASE 20.—M., 52. Third attack. (See Fig. 2.) Admitted Nov. 15th, 1927: R.B.C.'s, 740,000; Hb., 20 per cent. Patient very gravely ill; delirious; vomiting constantly; had really been sent into hospital to die. Was put on liver juice at once. Boots's liver extract, 15 g. daily, commenced on Nov. 28th (liver juice being stopped). Four days later reticulocytes had risen to 15 per cent., rise having started under liver juice. On Dec. 3rd daily dosage was reduced to 10 g.

CASE 21.—F., 45. First attack. (See Fig. 3.) On Nov. 14th, 1927, Boots's liver extract, 10 g. daily, commenced, when R.B.C.'s were 1,240,000 and Hb. 32 per cent. By tenth day reticulocytes had risen to 16·5 per cent. On

FIG. 3 (Case 21).



Nov. 29th liver extract was stopped and 4 oz. liver given daily, along with 4 oz. liver juice. R.B.C.'s rose to 3,000,000, but there progress appeared to be arrested. On Dec. 15th Boots's liver extract, 3 g. daily (and later 5 g.), were added to diet. Count rose to 3,800,000, and finally to 4,300,000.

CASE 22.—F., 27. Admitted to Royal Infirmary Oct. 19th, 1927, following confinement in mid-September. R.B.C.'s, 1,500,000; Hb., 33 per cent.; W.B.C.'s, 9000. 4 oz. liver and 4 oz. liver juice given daily. A month later R.B.C.'s were 2,500,000; Hb., 47 per cent. The slight degree of chronic nephritis which had been present since before confinement developed into an attack of acute Bright's disease (associated with a leucocytosis of 12,000), necessitating the temporary stoppage of whole liver diet. After a further month of modified liver diet, the count remaining stationary, 5 g. Boots's liver extract was added to the diet. After another month, R.B.C.'s were practically 4,000,000; Hb., 65 per cent. The conjunction of nephritis and leucocytosis is referred to below.

CASE 23.—F., 51. First attack. Liver diet (4 oz. liver + 4 oz. juice per day) started Oct. 18th, 1927: R.B.C.'s, 1,000,000; Hb., 25 per cent. After one month, R.B.C.'s, 2,500,000; Hb., 60 per cent. No improvement for next four weeks (owing to patient being unable to take more than quantity indicated above). Boots's liver extract, 5 g. per day, added to diet. Count immediately began to rise, reaching 3,700,000, and Hb. 60 per cent., in 12 days.

2. *Extract Prepared by British Drug Houses, Ltd.*

CASE 24.—M., 66. Second attack. Liver extract, 2 vials daily, started Jan. 20th, 1928.

Date.	R.B.C.'s.	Hb.	Reticulocytes.
Jan. 19th ..	890,000 ..	30 per cent. ..	6·5 per cent.
,, 23rd ..	— ..	— ..	16 ,,
,, 25th ..	1,290,000 ..	38 per cent. ..	9 ,,
,, 28th ..	1,610,000 ..	40 ,, ..	3 ,,
Feb. 1st ..	— ..	— ..	2 ,,
,, 7th ..	2,760,000 ..	65 per cent. ..	0·5 ,,
,, 20th ..	3,960,000 ..	70 ,, ..	0·5 ,,

During week before admission, this patient had eaten 1½ lb. of liver, which explains the high initial reticulocyte count and quick response.

3. *Extract Prepared by Burroughs Wellcome.*

CASE 25.—M., 48. Third attack. Liver extract, 2 vials daily, started Jan. 13th, 1928.

Date.	R.B.C.'s.	Hb.	Reticulocytes.
Jan. 11th ..	1,100,000 ..	26 per cent. ..	0·5 per cent.
,, 20th ..	1,060,000 ..	24 ,, ..	4·0 ,,
,, 21st ..	— ..	— ..	9·0 ,,

CASE 26.—M., 51. First attack. Extract started Jan. 27th, 1928 (2 vials daily).

Date.	R.B.C.'s.	Hb.	Reticulocytes.
Jan. 26th ..	2,540,000 ..	60 per cent. ..	0·5 per cent.
Feb. 2nd ..	2,890,000 ..	65 ,, ..	9·0 ,,
,, 7th ..	3,200,000 ..	75 ,, ..	2·0 ,,
,, 29th ..	4,240,000 ..	90 ,, ..	0·5 ,,

4. "*Hepatopson*" (*a Desiccated Liver Preparation, made by the Promonta Manufacturing Company*).

CASE 27.—F., 67. Second attack. Given 100 g. "Hepatopson" daily, starting Dec. 11th, 1927. Dec. 10th: R.B.C.'s, 850,000; Hb., 20 per cent. Reticulocytes, 3 per cent. Reticulocytes rose steadily reaching 30 per cent. on tenth day, returning to normal by twentieth day. Jan. 3rd, 1928: R.B.C.'s, 2,450,000; Hb., 60 per cent. No further improvement occurred during next two weeks. Daily dosage therefore increased to 150 g. Jan. 24th: R.B.C.'s, 3,050,000; Hb., 75 per cent. Feb. 1st: R.B.C.'s, 4,000,000; Hb., 80 per cent.

5. *Liver Extract Made by Eli Lilly and Co.*

CASE 28.—M., 63. First attack. Extract (equivalent to 500 g. liver daily) commenced Dec. 12th, 1927, when R.B.C.'s were 1,550,000 and Hb. 43 per cent. Feb. 1st, 1928: R.B.C.'s, 5,010,000; Hb., 85 per cent. Reticulocytes followed usual course. Patient could not eat liver at all, but had no difficulty with extract.

6. A German preparation, "*Hepatrat liquid*" (Nordmark), was, in the absence of any cases of pernicious anæmia, tried in two cases of secondary anæmia (Banti's disease, and chronic nephritis). The activity of the preparation was demonstrated by the production of a reticulocyte rise in both cases. In the case of the nephritic the reticulocytes reached 15 per cent. on the twelfth day of treatment.

Conclusion.

One of us has had a long experience of pernicious anæmia and of the remissions that can be produced by all the methods of treatment formerly in use. The impression formed of treatment by liver and liver extract is that its effects are more promptly, rapidly, and regularly produced than by any former method, although occasionally treatment by arsenic or sometimes no treatment at all may be followed by remissions as rapid in their commencement. The period of recovery is certainly shortened. The most striking example of this is Case 2 of the private series. The recovery is more continuous. The production of a colour-index below unity, which under previous methods of treatment has been found to occur in cases which are going to do well, regularly develops under liver therapy. The most important point, however, is that recovery is more complete. Formerly one had too often to be content with a count of about 3,500,000 R.B.C.'s; now an extra million or more may be confidently expected; the whole blood picture returns to the normal with much greater frequency and certainty, and apparently remains so indefinitely, so long as treatment is persevered with. Two cases have been seen whose treatment was begun in America; they are not included in the foregoing lists. The first had begun liver treatment in 1925 and continued it steadily. The blood was examined twice at an interval of about a year and was practically normal on both occasions. The second was seen once 18 months after treatment was begun and the blood was normal. Both were in vigorous health. This return to vigorous health is certainly

more frequent and complete—and, let us hope, permanent—than has ever been experienced as a result of previous methods.

It is important to notice that liver treatment is effectual at any age, and still more that it acts just as well in chronic cases as in acute ones. Cases 6, 7, 8, 10, and 11 of the private series had had arsenic ad nauseam in various forms, had ceased to respond to it, and could no longer tolerate it, but they answered just as promptly to liver as if they had been fresh cases. It appears to be immaterial to the success of the treatment whether the patient is in his first attack or has suffered several relapses. It seems to be a matter of indifference whether the patient is treated with liver or with the liver extracts which we have tested. All the latter seem to be efficacious, and it will be a matter of personal liking and convenience whether liver or the extract is chosen for treatment.

Is the treatment free from risk? In the great majority of cases it certainly is. Nothing more serious than an occasional temporary diarrhœa is likely to occur, and this can be dealt with by stopping fruit and vegetables for a few days. But it is to be noted that renal complications may arise, though their connexion with liver treatment is not definitely proved. One of our hospital cases had an acute nephritis and Case 11 died of uræmic vomiting and convulsions. One of us long ago pointed out that the only condition which will cause a persistent leucocytosis in pernicious anæmia is kidney mischief. In that case the leucocytosis should have been a warning, but the patient was in such magnificent health until the final collapse that the warning was disregarded. No pernicious anæmia comes to the post-mortem table with normal kidneys, but this is hardly ever evidenced by albuminuria. In cases with a persistent leucocytosis, it would probably be wiser to trust to liver extract alone, which contains no protein, and not give the large quantities of red meat advocated in Minot's original diet.

In the first few private cases one was inclined to give arsenic as well as liver, on the principle that it is unwise to throw away a crutch too soon, but that was soon found to be unnecessary. Hydrochloric acid is of value in improving appetite and hence may be used in combination with liver therapy. It is certainly not responsible for the remarkable improvement following the exhibition of liver, as equally good results are obtained in cases which have never received any acid.

Minot has formed the opinion that the nervous symptoms are not benefited by liver treatment, except in so far that as the muscles become stronger the patient can walk better. We are inclined to differentiate a little more. It seems to us that in cases in which the symptoms are of the tabetic type very marked improvement may occur, but in cases of the spastic type we have, so far, either seen no improvement or, as in Case 8 of the private series, a distinct increase of spasticity may supervene, possibly because the muscular tone is increased.

Part of this work was done under a grant by the Medical Research Council. Our thanks are due to those physicians of the Royal Infirmary, Edinburgh, who have kindly allowed us to make observations on their cases.

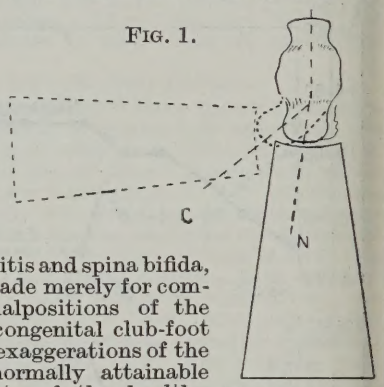
CLUB-FOOT: ITS NATURE AND TREATMENT.

BY A. WILFRID ADAMS, M.S. LOND., F.R.C.S. ENG.,
SENIOR ASSISTANT SURGEON, BRISTOL ROYAL INFIRMARY AND BRISTOL CHILDREN'S HOSPITAL.

ONE infant in every thousand is born with a foot fashioned in the form of a club, but in which, although there is deformity, there is no paralysis of muscles. A variety of distortions occur, and the remarks that follow are concerned chiefly with the common type—talipes equino-varus. To the mis-shapen feet due to palsy of the muscles, whether spastic as the result of the antenatal encephalitis of Little's disease, or flaccid as in anterior poliomyelitis and spina bifida, brief allusion is made merely for comparison. The malpositions of the various types of congenital club-foot are no more than exaggerations of the extreme points normally attainable by the movements of the healthy foot. They can be readily understood by reference to the accompanying diagrams. (Figs. 1–7.) The most marked derangement is at the mid-tarsal articulation, the normal mobility of which approaches the ball-and-socket type and includes pointing the foot inwards (adduction), and raising the inner margin of the foot (inversion). (Figs. 1–3.) In addition, though scant attention has been paid to it, flexion (cavus) is an element of this deformity and needs to be reckoned with. (Fig. 4.) Comparatively little movement occurs at most of the other joints, and the foot is therefore shown in the diagram as consisting of two main parts separated by the mid-tarsal joint. The extreme foot-drop (equinus) at the ankle-joint is an obvious feature calling for no further comment. (Fig. 4.) Function is poor in the club-foot. Even at birth only a small range of passive movement is possible, and time reduces this still further. The fixity is not due to muscular defect but to the foot being "cast in a faulty mould."

FIG. 1.



Adduction of fore-foot; angulation of astragalus. N indicates normal angle of 10° inward deflection of head and neck of astragalus. C shows angle increased in club-foot (30–40°).

FIG. 2.

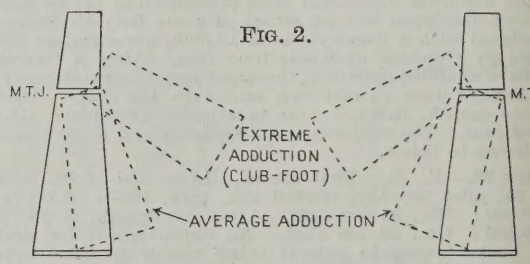


Diagram of pedal mechanism. M.T.J. = Mid-tarsal joint.

Ætiology is still a matter of speculation. In this series of 30 cases these facts deserve record:—

1. It occurs in 22 males (73 per cent.) and 8 females (27 per cent.).

2. There are 16 cases of double club-foot (53 per cent.) and 14 of single (47 per cent.).

3. The liability to associated defects is above the average—i.e., present in 4 (13 per cent.).

4. No evidence of hereditary or familial influence was found except that two cases came from one family.

5. Two patients, one of whom was also the subject of multiple ankyloses of both arms, had perfectly normal twin brothers.

FIG. 3.

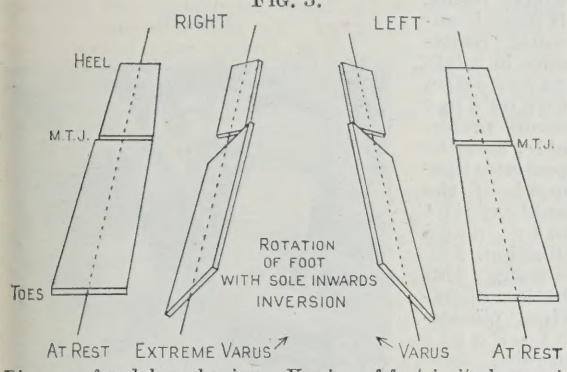

Diagram of pedal mechanism. Version of foot in its long axis. M.T.J. = Mid-tarsal joint.

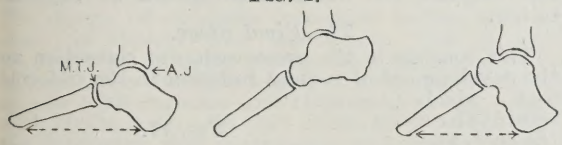
Anatomical Obstacles to Correction of Talipes Equino-varus.

1. Tight shortened capsules of joints on inner side of foot.

2. The very resistant tendo Achillis and ligaments at the back and inner side of the heel, which hold the os calcis twisted with its inner surface meeting the internal malleolus and the heel pulled up behind the ankle.

With age the deformity is accentuated and the

FIG. 4.



The left-hand diagram (average arch) shows the heel and toe spaced well; the middle one shows foot-drop at the ankle; whilst the right hand shows fore-foot-drop. M.T.J. = Mid-tarsal joint. A.J. = Ankle-joint.

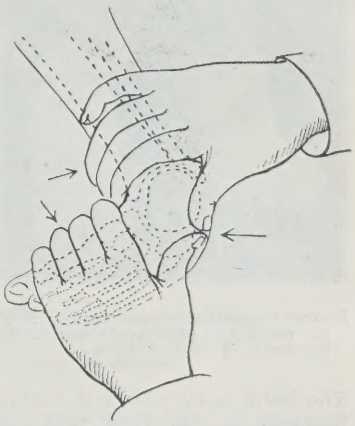
tarsus undergoes bony consolidation. Slight compensation is afforded by outward rotation of the femora.

Treatment.

It is said that no other deformity presents such a record of failures and incomplete cures. Such a reputation is a grave challenge to surgery. It seems to justify some remarks on a method, evolved during the treatment of a series (30 patients) of cases of talipes equino-varus, which ensures a well-shaped foot. A long, hard struggle is involved, but at the end there is the encouraging and cheerful assurance that muscles of balanced power are present and ready to work the re-formed foot. Though surgery has, since the days when subcutaneous tenotomy was started by Stromeyer, come to handle the advanced cases still more heroically, the best results naturally follow when the cripple is caught at birth. Then the structures are tender and yielding and there is no osseus tissue to remodel. It is to these early cases especially that the following method applies. Patience and tenacity on the part of the surgeon are demanded to an unusual degree. It is impossible to overstress the preliminary warning that unless he can win and retain the steady coöperation of the parents from the start he will come short of success, despite full knowledge and skill. The mother must be clearly told at the outset that active treatment for 12 to 18 months, entailing regular and frequent visits, will be necessary, and a further period of remedial exercises and supervision for two to three years. Otherwise months of tedious toil will be spent in vain, and the golden opportunity of early infancy will be gone. As a final persuasion it may be added that the treatment inflicts no wound beyond a trifling puncture of the skin; but neglect will lead to the necessity for a severe operation to rectify the foot later on.

The main steps in treatment are: 1. Over-correction of the deformity by manipulation. 2. Maintenance of rectified position for some months. 3. Exercise and constant supervision for years.

FIG. 5.

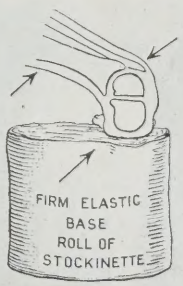


Corrective hand grip. Bone outlines dotted. Astragalus seen to underlie lateral convexity of foot against which pressure is made by the thumbs.

Treatment should commence at birth. Instructions are given for the foot to be held twisted outwards at suitable times during the day. At the second week of life the method of continuous rectification is instituted, as better adapted to the circumstances of limited time and means of average parents.

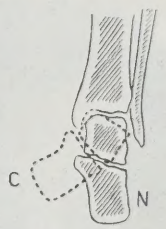
A general anæsthetic is used. Three elements only in the deformity receive attention in the first stage. When these are corrected the cure of the remaining foot-drop follows more easily. They are: adduction, inversion, and cavus. The foot is held with the thumbs pressed on the outer aspect of the astragalus, which becomes a fixed fulcrum on which leverage is obtained to force outwards the fore-foot and leg gripped by the fingers of the left and right hand respectively. Steady pressure is maintained for some minutes. This overcomes adduction. (Fig. 5.) At the same time the concavity on the inner side of the ankle is flattened out by the counter-pressure of the table on the inner margin of the heel. This brings the os calcis into its normal position underneath the tibia. (Figs. 6 and 7.) The element of cavus will obviously be reduced by this same corrective pressure. The shortened ligaments begin to yield and allow the foot to be held without effort in partial correction. It is so retained, and a strip of 1 inch wide zinc oxide strapping is laid along each side of the leg (Nutt). These strips are about 3 inches longer than the limb and at the foot are passed through stockinet with which the leg is protected. Occasional sores may call for ointment dressing. Plaster-of-Paris bandages are applied from the foot to the

FIG. 6.



Straightening bow-ankle. Arrows indicate corrective pressure applied to straighten the bent tibio-tarsal region and bring tarsal bones out into vertical alignment with tibia.

FIG. 7.



Coronal section of ankle (left). N = Normal vertical subtibial position of hind tarsus (very slight knock-ankle). C = Club-foot. Subtibial tarsal bones drawn inwards to submalleolar (marked bow-ankle).

knee, and among the turns are caught the two projecting ends of strapping. By this means is overcome, with few exceptions, the objectionable tendency of plaster splints to slide down the leg. If it fails, the plaster must reach to the lower third of the thigh. The splint needs moulding and supporting until hard.

If resistance calls for it I perform syndesmotomy of the talo-calcaneo-scaphoid capsule and fore part of the deltoid ligament through a puncture of the skin with a tenotome in front of the internal malleolus. The same site serves for tenotomies of the tibiales, but experience seems to show that these are superfluous, and possibly even harmful as contributory to flat-foot.

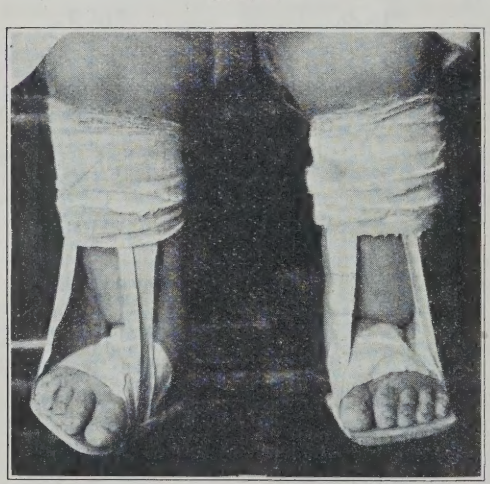
FIG. 8.

Double congenital equino-varus. Feet in retentive plaster-of-Paris after tenotomy of tendo Achillis.

This treatment is carried out entirely in the out-patient department and the mother is cautioned, before leaving, about signs of undue compression by the bandage. The toes should be inspected next day. The baby is to return in two weeks, and the night previous to the next visit the mother soaks off the plaster, bathes the leg and leaves it unsplinted. By this brief freedom retarded growth, one of the drawbacks of immobilisation treatments, is largely averted, as the foot has time to relax.

Every two weeks the foot is wrenched and the plaster renewed, until at about four months the unsupported foot remains in the valgus position. Two or three wrinkles in the skin anterior to the external malleolus afford confirmation that the underlying astragalus has receded to the inner aspect of the foot. Mild eversion of the os calcis is a welcome sign.

FIG. 9.

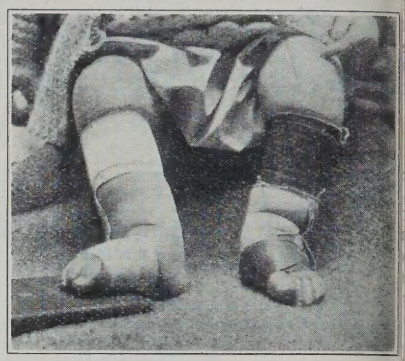


Double talipes equino-varus feet with sole-plates and retentive strapping.

So far no attention has been paid to the equinus. It is now, however, when the os calcis is in its normal position below the astragalus that this can the more advantageously be treated. To correct this drop-foot the tendo Achillis is divided subcutaneously just above the heel, and the foot forcibly dorsiflexed. In some cases one is tempted to omit the use of the knife, as the foot may seem to yield by manual force without tenotomy. This is deceptive, for, although vigorous upward pressure on the sole might still seem to produce dorsiflexion, it would do so not by drawing the heel down but by tearing the plantar ligaments in the mid-foot and so angulating the foot at the medio-tarsal joint. A V-shaped foot would result.

If there is unusual resistance in a late case, open tenotomy seems preferable, and the posterior ligament of the ankle-joint may need division. Following this little operation, plaster-of-Paris applied over sterile dressings and stockinet (Fig. 8) is renewed with increasing correction every few weeks until at the sixth to eighth month the foot's natural posture when released is slight calcaneo-valgus.

FIG. 10.



Double equino-varus corrected and with retentive strapping applied, but no sole-plate.

At the conclusion of this stage of treatment is the "fool's paradise," for, to the mother, the foot appears well corrected and further irksome visits superfluous. But many months must elapse before the mis-shapen bones can grow to fit snugly into the corrected position and stabilise the cure. This should be explained to her.

The Final Stage.

This consists in the preservation of correction and the development of normal function in the re-formed foot which establishes the cure. The foot is maintained in over-correction by strapping, combined with a light wooden sole-plate. (Fig. 9.) If strapping alone is used (Whitman), its upward pull is confined to the instep instead of spreading over the whole sole. (Fig. 10.) This would further induce the cavus deformity already noted as inherent in club-foot. (Fig. 4.) It is manipulated into extreme over-correction at daily exercises and whenever the parent finds opportunity. During the next few weeks it is time to take stock of the situation and assess the effect of treatment, as to whether there may be an excessive abduction of the foot and pes planus or, what is much more frequent, a tendency to relapse. Either of these extremes, appropriately dealt with at this stage, can be controlled. At about 12 months, according to the development and

FIG. 11.

Double equino-varus corrected and wearing retentive shoe with day over-shoe.

function of the parts, the foot is measured for special night shoes and day over-shoes. (Fig. 11.)

Meanwhile, the child attempts to walk, exercises are continued, and during the second year boots are fitted, which may need special features if relapse threatens. Where the child attends regularly there is seldom need for the surgeon to do more than supervise, but further enforced splintage in plaster or even tenotomy are not infrequent necessities. The objection that growth is liable to be retarded by the earlier months of immobilisation calls for an intensive course of remedial exercises to make good any deficient power. The infant is now at an age to coöperate in simple exercises.

Difficulties in Treatment.

Among the difficulties to contend with the chief is non-coöperative parents. This may be due to the fact that they cannot, from lack of brains, time or money, or simply will not, follow expert advice. Thus, the parents of one case refused to allow their child to stay in hospital, and it was impossible to pursue the treatment for more than a few months, since they were denizens of a Welsh mountain fastness. In my cases this failure to maintain attendance has been almost the chief stumbling-block. Often bronchitis, whooping-cough, one of the exanthemata in the family, a twin babe or the advent of another infant interferes. It cannot be repeated too often that an almost unbroken record of attendances is necessary if complete success is to be ensured. A further hindrance is that the plaster-of-Paris splints are apt to slide off if the leg is fat and shapeless. Methods of overcoming it have already been mentioned. In such cases, too, especially in the early months and with less scrupulous parents, the skin is liable to excoriation which may call for temporary remission of plasters. Also, if the plaster slips and the mother is unable to bring the child within the next day or two a friction sore may develop.

The danger of excessive correction leading to pes planus has already been mentioned. One of my cases shows it. Intoeing is frequently noticeable in a mild form when the child begins to walk, but tends to disappear with exercises and thickening of the outer margin of the boot. No part of the foot escapes the varus deformity, and metatarsus and hallux varus need their full share of correction. This they are apt to miss if the continuation of the plaster to the end of the inner margin of the big toe is omitted. An unwelcome proof that the hallux is receiving due outward pressure is the resulting tendency for the second toe to be squeezed upwards, overriding its fellows. This can be avoided and the toe kept in line with the rest of the row if the orifice is made shallow in moulding the plaster. By this means the beneficent outward pressure on the big toe is transmitted from one toe to the other throughout the whole row. Intoeing and traces of equino-cavus have proved the most frequent residue of the deformity. Concentration on the feet must not allow the surgeon to ignore intercurrent genu valgum.

Additional Measures in Late Cases.

A very useful and permanent corrective to varus tendon transplantation to maintain the correct position. This can easily be effected by taking the tendon of the tibialis anticus (or part of it) to the base of the fifth metatarsal. Bankart has found a silk ligature passed along the same path an efficient retainer, though one cannot avoid a dislike for the insertion of irritating foreign matter.

In cases of late equinus and associated cavus a modified Steindler's operation, exposing the tight capsules of the ankle- and tarsal-joints on the inner side coupled with forcible wrenching into well-marked valgus, is a useful measure combined with secondary tenotomy of the tendo Achillis and transplantations of the extensor longus hallucis to the head of the first metatarsal.

In the worst cases, or even in children as young as 3 years where there is difficulty in regular visits, a cuneiform tarsectomy with the base of the osseous wedge on the supero-external aspect of the mid-tarsus answers well. The foot is fixed in plaster-of-Paris for two to three months.

Astragalectomy has its supporters, while Openshaw advocates removal of the fore process of the os calcis.

In all these cases there is need of subsequent treatment which is the more prolonged the worse the condition is when the infant is first seen.

Finally, in adults with gross deformity, numerous callosities and impaired circulation, the kindest measure of relief is likely to be Syme's amputation as advised by Rankin.

Among the many valued collaborators in this work I owe a special debt of gratitude to my clinical assistants, Drs. C. I. Ham and W. O. H. Evans, and to the surgical out-patient nurse at the Bristol Children's Hospital for her unfailing devotion.

Clinical and Laboratory Notes.

A CASE OF INFECTION OF THE MENINGES AND BLOOD STREAM BY *BACILLUS MUCOSUS CAPSULATUS*.

BY W. RUSSELL BRAIN, M.D. OXF., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL;
AND
F. C. O. VALENTINE, M.R.C.P. LOND.,
ASSISTANT DIRECTOR OF THE CLINICAL LABORATORIES, LONDON HOSPITAL.

THE following case has come under our observation.

In November 1923, a man, aged 22, was admitted to the London Hospital having had a discharge from the right ear for eight days. The right tympanic membrane was red and showed a central perforation. An incomplete mastoidectomy was performed, the sinus and dura mater not being exposed, and the patient appeared to make a good recovery.

In July, 1927, he was readmitted to the hospital and stated that six months previously the discharge had recurred. There was tenderness on pressure over the scar of the previous operation. A complete mastoidectomy was performed, the dura being exposed but not the sinus. The patient complained of giddiness for a few days following the operation, but made an uninterrupted recovery. On leaving the hospital he went to a convalescent home and, on returning home, developed a severe cold in the head.

On Sept. 26th, 1927, he was readmitted to hospital with a complaint that for 14 days he had suffered from severe headache and intense pain at the back of the neck. On admission his temperature was 103° F., and he had a rigor in which it rose to 104·5°. He was drowsy and complained of severe headache. There was marked rigidity of the posterior cervical muscles and Kernig's sign was positive. There was slight bilateral papilloedema. The pupils, ocular movements, and cranial nerves were normal. As far as could be judged there was no loss of voluntary power. The tendon reflexes were all extremely sluggish and the plantar responses were flexor. There was a mucopurulent nasal discharge. On lumbar puncture the cerebro-spinal fluid was found to be turbid and under greatly increased pressure. The temperature remained between 103° and 104·5°; the pulse 100 to 120, and the respirations 30. The patient was removed from hospital on the fifth day by his friends, and died two days later.

Ten c.cm. of cerebro-spinal fluid was removed for examination. The fluid was cloudy and formed a large cobweb on standing. Films showed pus with numerous Gram-negative bacilli. resembling *Bacillus coli communis* in appearance, and showing no evidence of capsules. Cultures in liquid media showed a diffuse growth, and on solid media large sticky colonies. The organism, a non-motile Gram-negative bacillus, formed acid but no gas in dextrose, mannite, and lactose, and failed to ferment inulin and dulcite. Milk was acidified but not clotted. Gelatin was not liquefied. As a test for virulence 1 c.cm. of a 24-hour broth culture was injected into the peritoneal cavity of a guinea-pig which died three days later. General fibrino-purulent peritonitis was found at post-mortem, and the organism was identified in films and recovered in culture from the peritoneal exudate and from the heart's blood. The films gave definite evidence of a large capsule surrounding the organism.

A blood culture taken from the patient on the same day as the spinal fluid yielded a bacillus apparently identical with that found in the spinal fluid.

It seems justifiable to use the name of *B. mucosus capsulatus* in describing this organism. The bacillus appears to be closely allied to Friedländer's pneumobacillus, the chief cultural distinction being the fermentation of carbohydrate without gas formation in the case of *B. mucosus*. The organism belongs to a group, the members of which show very varying degrees of pathogenicity. General infections, with meningeal involvement, by bacilli of the Friedländer type are occasionally met with, but a mucoid bacillus of these cultural characters has not previously been isolated in these laboratories, either from the blood or the spinal fluid. A further point of interest in this case is the apparent recovery after operation, followed some six weeks later by the development of an infection which proved fatal.

A NOTE ON TWO SIMPLE TESTS FOR IMPURITIES IN ANÆSTHETIC ETHER.

BY EDWIN B. ROBINSON, M.SC. MANCH.,
LATE SCHUNCK RESEARCH ASSISTANT AT THE UNIVERSITY OF MANCHESTER.

IN recording some abnormal results obtained when using certain samples of ether for anæsthetic purposes (THE LANCET, 1927, i., 1117), Dr. S. R. Wilson concluded that the abnormalities were due to the presence of impurities—probably acetaldehyde and "peroxides" in the ether. He based his conclusion partly on reports on chemical tests carried out in the chemistry department of the University of Manchester. These reports indicated, as Dr. Wilson states, a close relationship between the presence of impurities in the ether and the previously observed undesirable clinical properties of the samples submitted. The writer, as Prof. A. Lapworth's assistant, did the actual chemical tests on Dr. Wilson's samples. It is thought worth while to describe two of them in detail, as they are easy to carry out and may prove useful to anæsthetists. Positive results obtained on applying these tests to samples of ether will at least give warning that the samples are to be suspected.

The two tests advocated for rapid and simple use were first described by W. Wobbe,[1] but neither are given by the British or United States Pharmacopœias.

Description of Tests.

Test A.—The test solution consists of an alkaline-ammoniacal solution of silver nitrate. Unfortunately, as usually made, the solution is very unstable, and in the course of one or two days begins to decompose with the formation of a black precipitate. On account of this it is advisable to keep the three constituents of the test solution in separate bottles and mix them in the required proportions immediately before use. This is best done as follows:—

Silver nitrate (24·0 g.) is dissolved in water (60 mils.) and the clear solution kept in an amber-coloured, glass-stoppered bottle (*solution 1*).

Aqueous ammonia of specific gravity 0·923 is made by diluting 50 mils. of conc. aqueous ammonia (sp. gr. 0·88) to 86 mils. The solution is kept in an ordinary stoppered bottle (*solution 2*).

Pure caustic soda sticks (30·0 g.) are dissolved in distilled water (70 mils.) and the solution kept in a bottle provided with a tightly-fitting rubber stopper (*solution 3*).

The test solution is made by mixing together 8·6 mils. of solution 1, 13 mils. of solution 2, and 3 mils. of solution 3.

The ether is tested by adding 10 mils. of the sample to 2·5 mils. of the test solution contained in a clean test-tube. If more than minute traces of aldehyde are present a black ring will appear almost immediately at the interface of the two liquids, and on shaking a black precipitate will form in the aqueous layer. On standing, a silver mirror is sometimes formed. If the quantity of aldehyde present is negligible no precipitate will form, even after standing for several hours; a brownish coloration may be formed, but this may be neglected.

Test B.—The test solution consists of a mixture of equal volumes of 50 per cent. potassium iodide solution (*solution 4*) and 1 per cent. phenolphthalein solution (*solution 5*). These solutions should also be kept in separate bottles. To test for peroxides, solution 4 (1·25 mils.) is mixed with solution 5 (1·25 mils.) in a clean test-tube and 10 mils. of ether added. On shaking for a short time (30 secs.–2 mins.) a red colour becomes apparent if the ether contains an appreciable quantity of peroxides.

Note.—Both in preparation of the solutions and the carrying out of all the tests, it is essential that clean apparatus should be used and care taken to conform rigidly to the quantities given.

Discussion.

In Dr. Wilson's paper mention is made of G. Middleton's "peroxide" test which is used by the British Drug Houses.[2] This test is very trustworthy in the hands of a worker who has had considerable experience in chemical manipulation and has at his disposal the necessary time and reagents to carry it out, but most anæsthetists would find it impracticable for general use. On the other hand, both the tests put forward by Wobbe are rapidly carried out on small quantities of ether and the reagents required are in general use amongst anæsthetists and most medical practitioners.

The two tests differ in sensitiveness, A being more sensitive than B. Test A will detect very small concentrations of acetaldehyde in ether and, very probably, *the reagent* will also be acted on by peroxides and many other bodies. That it is possible, however, to prepare and store ether which does not respond to this test has been shown by testing certain samples of commercial anæsthetic ether.

Statements have been made that concentrations of acetaldehyde less than 0·5 per cent. have no deleterious effects during anæsthesia. Middleton,[2] however, has shown that the rate of formation of peroxides in ether is doubled in the presence of acetaldehyde. Thus a sample of ether containing less than 0·5 per cent. of acetaldehyde when bottled and sealed, may even though great precautions are taken in storing become much more highly contaminated in course of time. The observations recorded by Dr. Wilson show that the peroxide and aldehyde content of ether is rapidly increased when oxygen is bubbled through it in an ordinary Shipway apparatus. It is, therefore essential that ether which is to be used for anæsthetic purposes should be tested in some way immediately before use.

Test B, for peroxides, does not respond to a solution of pure acetaldehyde in ether. Hence it is not sufficient to apply test B alone to samples of ether intended for anæsthetic purposes. The test is not so sensitive as that described by Middleton, but is much simpler to carry out. In the present state of knowledge samples of anæsthetic ether which contain sufficient peroxides to respond to test B should be viewed with great suspicion.

In conclusion, the writer wishes to acknowledge his indebtedness to Prof. A. Lapworth, F.R.S., for his help and criticism during the time the work was proceeding and for facilities enabling it to be carried out.

AN UNUSUAL CASE OF APPENDICITIS.

BY W. ALFORD TAYLOR, M.B. LOND.,
HON. SURGEON, ROYAL BUCKS HOSPITAL, AYLESBURY.

THE following case came under my care at the hospital on Feb. 14th of this year.

A farm labourer, aged 26, complained of generalised abdominal pain. He had not felt well since Christmas and had had three attacks of colicky pain across lower abdomen at intervals of a few days, each lasting for three days, but not severe enough to stop him working. Three days before admission he had vomited once. The bowels had been open regularly except on the day of admission.

On examination the temperature was 102·2° F., the pulse-rate 106, and the respiration-rate 28. The tongue was coated and dry. He had generalised abdominal tenderness, more marked in the right iliac fossa. There was rigidity of the right rectus, and hyperæsthesia over Poupart's ligament. Per rectum nothing abnormal was detected. Under an anæsthetic a small, hard, movable lump was palpated 1½ in. mesial to the anterior superior iliac spine. The abdomen was opened by Battle's incision, and the appendix was found completely enveloped in a sheath of omentum, which bled freely, but was returned to the abdomen after the insertion of hæmostatic sutures. The appendix was acutely inflamed and presented a drumstick appearance caused by a spherical swelling ¾ in. from the cæcal end. The appendix was removed by the usual method, the stump being buried and the abdomen closed without drainage. The patient made an uninterrupted recovery.

The appendix was found to contain an intact barcelona nut, of full size, and showing indentations caused by teeth. The patient denied having eaten any nuts since Christmas.

Medical Societies.

HARVEIAN SOCIETY OF LONDON.

THE TREATMENT OF ULCERATIVE COLITIS.

A MEETING of this Society was held on April 19th, with the President, Dr. HERBERT FRENCH, in the chair.

A discussion on the Treatment of Ulcerative Colitis was opened by Dr. H. LETHEBY TIDY from

The Medical Aspect.

He said that colitis was a condition in which there was diarrhœa and the stools contained blood and mucus. This might occur without ulceration, as in bacillary dysentery, or ulceration might supervene without any change in the symptoms. It was, however, practically certain to be present in a patient who had suffered from these symptoms for any length of time. The onset might be dramatically sudden, but more often, in civil practice, the doctor saw the patient after his condition had drifted on for a few months or, occasionally, for a few days or weeks. The chronic case might have acute exacerbations.

Certain *general principles of treatment* must be accepted whatever other methods were adopted. First and foremost, the patient must be kept warm. Warmth checked peristalsis and had certain general effects which made it of the utmost importance. In Dr. Tidy's experience the patient with the warm moist skin would recover; it had rightly been said, "the dysenteric who sweats never dies." There was forty to fifty times the difference in mortality between the warm and the cold patient. Mere confinement to bed was not enough; the extremities must be wrapped in wool to wrists and ankles, even in a tropical climate. The second cardinal principle was that the patient must be given fluid—not in large draughts, but as a medicine. During the acute stage he should take 1 or 2 oz. every 20 minutes while awake, with a total of 4 or 5 pints in the 24 hours.

The alternatives of treatment were by injection, by the mouth, by vaccines, and by serum. Dr. Tidy had found drugs by the mouth of little value, with the exception of aromatic sulphuric acid and charcoal. It was utterly wrong to give morphia in any circumstances whatsoever. An injection would check the diarrhœa and was therefore very hard to resist, but it must not be given. It was doubtful, too, whether the drug was ever justified by the mouth, even in the form of such preparations as chlorodyne. Cases that would clear up like an ordinary diarrhœa would clear up just as well without morphia, and severe cases ought not to have it. Dr. Tidy could not persuade himself that any valuable results had followed the use of vaccines. Serum was of enormous value for a very short time after the onset of bacillary dysentery, but not in the later stages. It was therefore not indicated in the ordinary chronic colitis of civilian practice. There were three ways of treating the rectum—by starch and opium enemas, by colonic washes, and by medicated enemas. The mortality would be halved at once if medicated enemas could be abolished; they could do very grave injury and must be withheld to the very end of the treatment.

The first measure should be the starch and opium enema, with a maximum volume of 4 oz.—3 oz. for the average man and 2 oz. for a woman—and with a dose of ½ to 2 drachms of the tincture of opium. The fluid should be administered through a soft rubber No. 10 catheter and funnel, with 6 to 8 in. of pressure. Its effect lasted about 12 hours, and the enema should therefore first be given at night, to ensure rest. It must not be given more than five times a week and never on more than three consecutive days. If the anus and rectum were once allowed to get irritated they would reject the enema and the whole treatment would be put back for a fortnight. If after three weeks of this treatment the number of stools had been reduced to half, the practitioner might count himself lucky, and might then pass to the second stage of colonic washes. These might consist of any bland fluid—for instance, a drachm to the pint of sodium chloride or 2 drachms to the pint of sodium bicarbonate. The wash should be given in the same way as the enema with a pressure of 12 to 18 in.—never more than 2 ft. Two pints of fluid should be used and should never take less than half an hour to administer. The patient should lie on alternate sides during the administration. There was no doubt that the fluid reached the cæcum when given in this way. Very few patients would stand more than three washes a week, and they should never be given them on more than two consecutive days, with a maximum of four one week and three the next. It would often be necessary to return for a time to the starch and opium enema to keep down the number of stools. In contradiction to the advice of the text-books, these two forms of treatment must be continued for six or eight months before medicated enemas were started. The medicaments irritated the colon and must be the final curative stage of treatment, which was not reached until there were consistently fewer than five motions a day. For a medicated enema albargin was the best preparation in a dose of ½ drachm to 30 oz. of saline or tap-water; 25 oz. should be given very slowly after a colonic wash, of which at least half must have been returned. The best routine was to give a wash between 6 and 9 A.M. and the enema about 10 A.M. The absolute maximum was six in a fortnight, followed by a week's rest. Any attempt to rush the treatment defeated its own object, and practitioner and patient alike must realise that the whole treatment was a matter of many months, usually eight or twelve. No colon which had been through this trouble was going to be "cured," any more than an amputated leg could be "cured," but most patients at the end of the course passed no more than two or three motions a day and could live active lives. "Cure" might be interpreted as not more than three or four fairly formed motions daily. There was no justification

whatever for the appalling mortalities recorded. Errors were due to reliance on medicated enemas and drugs by the mouth and to haste.

Ætiology and Pathology.

Mr. LIONEL NORBURY said that the dysentery bacillus had been incriminated as the cause of ulcerative colitis, but against this was the absence of history of infection, of infectivity, and of the bacillus in the stools, as well as the fact that the serum of patients did not agglutinate the Shiga bacillus, nor did the patient benefit from antidysenteric serum. Many different organisms had been isolated. Constitutional diseases, such as chronic nephritis, might be complicated by ulcerative colitis. In several cases achlorhydria has been a feature, and these patients had improved on a course of hydrochloric acid. Shortage of calcium in the blood and of vitamins might be predisposing causes. The pathology varied from œdematous areas with vascular granular patches in the colon to small punched-out ulcers, which might run together and form large areas. Œdematous masses of mucous membrane might be isolated and simulate polypi. The ulcers were not undermined and were usually superficial, so that little scar tissue resulted. Nevertheless, they might spread to the peritoneum, producing fistulæ and perforations. In many cases there was no characteristic ulceration, but only raw bleeding areas denuded of epithelium. The disease was one of early adult life and the sexes were about equally affected, though at St. Mark's females had seemed to preponderate. Death resulted from hæmorrhage, exhaustion, perforation, or peritonitis. The diagnosis was made on the symptoms and on the appearances seen through the sigmoidoscope.

The Surgical Treatment.

The treatment, after rest and warmth and suitable measures directed to the cause, if this could be ascertained, consisted of removal of septic foci and a liberal diet, including vitamins, fats, and fruits. Drugs for alleviation of symptoms included zinc oxide pills, 3 grains thrice daily; 15 minims of castor oil in gelatin capsules, kaolin, bismuth, opium, kerol, dimol, and animal charcoal. Vaccines might be made from organisms taken from the granular surfaces (Dr. Cuthbert Dukes had devised a special sucker for this purpose) or from the urine. Lavage should be administered in the knee-elbow position, or with the patient on alternate sides and the pelvis raised. Hypertonic saline, silver, albargin, sanitas, or kaolin could be used. Blood transfusion was useful for severe cases. Zinc ionisation gave good results with some patients, although the sigmoidoscope showed that no real cure had been brought about. If the case did not readily respond to ordinary methods appendicostomy should be performed, as it was obvious that better irrigation could be obtained from above than from below. If for any reason appendicostomy was unsuitable a valvular cæcostomy might replace it. Two to four quarts of fluid should be washed through the opening twice daily, and very acute cases might be treated with continuous irrigation. To rest the colon a right colostomy or cæcostomy was necessary, but the fluid fæces at this level made the nursing difficult and stenosis was very likely to follow. In these respects a right lumbar colostomy was better. Excision was usually impracticable because of the debilitated condition of the patient. While the symptoms might improve considerably, the sigmoidoscope usually showed that the condition was little altered. Ulcerative colitis was one of the most serious conditions of intestinal disorder and one of the most difficult to cure, requiring several years of regular irrigation through an appendicostomy.

Bacillary Ætiology.

Dr. BELLINGHAM SMITH argued that the condition was an endemic dysentery, of which we had not yet recognised the causative organism. In a number of his cases an unknown non-lactose-fermenting bacillus had been isolated. It was well known that the Shiga bacillus was obtainable from all cases of dysentery in the first 72 hours, but the number of positive results rapidly fell. Since few cases of ulcerative colitis were seen early, the organism was not likely to be found often. He agreed with previous speakers about drug and local treatment, but thought that sodium sulphaté had value in the early stages, combined with spirit of aromatic ammonia and ginger. Adrenalin added to the opium enema was useful. The condition was practically incurable and could only be relieved. Of his 46 cases 24 had died, 13 under medical and 11 under surgical treatment; 16 had improved, and three had much improved.

Mr. C. P. G. WAKELEY pointed out that perforation was nearly always in the cæcum or right colon. Treatment should be based on sigmoidoscopic examination. If the ulcers were shallow and the mucous membrane œdematous, medical treatment would give the best results, but it could do no good if the ulcers were deep and going into the wall of the bowel. Then cæcostomy or right colostomy would give great benefit. After six months of medicated enemas the patient was a miserable creature with tenesmus and a patulous anus, and would get great relief from cæcostomy. Appendicostomy did not give very good results. He preferred hypertonic saline at 100° F. for irrigation from above. The condition was not so incurable as was made out if early diagnosis and treatment were instituted by the use of the sigmoidoscope.

Sir JOHN BROADBENT supported the bacillary ætiology, quoting recent work at the Mayo Clinic, where a Gram-positive lancet-shaped diplococcus had been isolated and had given satisfactory experimental results. Vaccines of this organism had given 60 per cent. of recoveries. He had seen cases which had improved remarkably and thought the claim worth investigation.

The PRESIDENT described two cases which he had hoped to show. Both had been in an appalling state after years of medical treatment; both had recovered after colectomy and resumed active life. The only good results he had known had been from colectomy, but surgeons were loth to perform it and patients to undergo it. There were probably many different causes of the condition, and in the later stages it could not matter what the original cause had been. Cure meant getting the patient into such a state that he no longer needed medical attention. He had never seen cure after any kind of treatment in a case of more than six months' standing. Any treatment might give relief, but relapse followed. It was remarkable that the condition never appeared anywhere but in the colon.

Sir WILLIAM WILLCOX said that many cases were hopeless from the first. Post-mortem examination showed that the condition was very like bacillary dysentery, and that it might spread up the first few inches of the small intestine. He agreed that the original cause was a bacillus, but this was swamped by secondary infections in a few days. Treatment must depend on the stage of the disease. Hypertonic intravenous saline was useful for those cases where the diarrhœa was choleraic.

Dr. TIDY, in reply, said that the vast bulk of cases were no doubt due to some organism, and he was sure that the Mayo coccus was the "enterococcus" of Sir Thomas Houston. Nevertheless ulcerative colitis might be due to many different things.

Mr. NORBURY also briefly replied.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society held at the Guildhall, Bath, on April 20th, the acting President, Dr. E. H. SNELL being in the chair, a discussion took place on the

CAUSES OF THE DECLINE IN TUBERCULOSIS MORTALITY.

Sir ROBERT PHILIP (Professor of Tuberculosis, Edinburgh University), in the opening paper, traced

the gradual growth of the fight against tuberculosis since the first dispensaries were started in the last century. Thus had arisen a more searching investigation of the early signs of infection and a recognition of tuberculosis as a "household disease." The examination of contacts had shown how frequently the disease was contracted in childhood and how much resistance varied. Tuberculosis schemes had been gradually evolved and improved as time went on. In Edinburgh the ordinary medical graduate, as well as the D.P.H. student, received special courses in tuberculosis work. The paper was illustrated by charts showing the change in the tuberculosis mortality since 1871 in Scotland, England and Wales, and Ireland respectively, in the whole population, in each sex, and at each age-period. Sir Robert Philip claimed that the decline in Scotland had been steady and uninterrupted. The drop in mortality was greater than that in the death-rate as a whole. The decline had occurred in other countries and had been greatest where the effort was greatest. In Paris and Vienna there was a marked improvement and in the arrondissements of France the result varied with the activities brought into play. Denmark had the lowest rate in Europe, and the claim was made that this was due to the special efforts made. In New York effort had produced a great decline and the urban districts in that State were now better than the rural. Similarly, the tuberculosis rate in the Highlands of Scotland was high as compared with the Lowlands. Numerous factors, of course, had been at work—sanitary improvements during the last 80 years; better education; better housing and working conditions; the effect of the Health Insurance Act, of medical inspection of school-children, of maternity and child welfare work; and of a coördinated health service. Everything that reduced the general death-rate also reduced the tuberculosis rate. He claimed, on the other hand, that the work done to attack the special problem had been of great value and had, in addition, aided progress in general public health matters, and led to improved environment as well as limitation of infection. Early discovery of cases and early treatment were very important. His experience with cattle and the effort to secure tubercle-free herds and open-air treatment for cattle was similar. For man they needed both exclusion of infection and the building up of resistance. They must be patient in appraising and not expect quick results. There had been much saving of life in childhood and among young adults.

Dr. W. M. WILLOUGHBY (M.O.H., Port of London) made an interesting comparison between efforts made to produce a wheat immune to rust, and what had been taking place in our population with regard to tuberculosis. Urbanisation had caused tuberculosis to be rife, and there had been at first a rapid sweeping off of the susceptibles. The rate of decline of the tuberculosis death-rate was now slowing down because susceptibles were less numerous and immunity was increasing. Now, when the endemic prevalence was tailing off, was the time for increased preventive effort. The decline had been temporarily retarded by the want of fat during the war. Resistance to tubercle was quite a special thing. It was perhaps intrinsically greater in the female sex and was also related to the constitutional liking for and ability to digest fat. It was, in fact, hereditary.

Dr. E. L. COLLIS (Mansell Talbot Professor of Preventive Medicine, University of Wales) said that of the three types of tuberculosis the decline in mortality had been most in the infant, less in the early adult, and least in the middle-life type. He inquired: Was any immunity acquired by fighting and defeating the tubercle bacillus? He suggested that the young adult curve was not lessened by infant immunity and that phthisis at ages 15–30 was largely a problem of nutrition. Malnutrition really broke down any immunity acquired in infancy. Tuberculosis favoured by alcoholism was evident chiefly in early middle life. In several occupations the prevalence of tuberculosis was chiefly a matter of opportunities for infection—e.g., printers, tailors, and bootmakers. The printing trade was improving. In such trades the exclusion of the infectious worker was the important thing. In the late middle-life type silica dust and the wear and tear of life wore down the immunity. Further reduction was to be expected in the late phthisis. In the early (15–30) type the reduction was due chiefly to the lessening of infection, to the increase in real wages, and to less wear and tear; and a still better result was to be expected from further control of infection and, very especially, from improvement in dietaries. We must control and segregate the infectious cases. The death-rate from phthisis at ages 45–55 in males had only fallen pari passu with the general death-rate. Amongst other illustrative charts Dr. Collis showed one which demonstrated the close correspondence between the fall in the phthisis rate and the rise in real wages. The rise in the female rate during the war was only in the early adult age-period and was due to nutritional causes.

Dr. M. GREENWOOD (Professor of Epidemiology and Vital Statistics, University of London) pointed out that the fall in the Scottish phthisis death-rate was not a straight line, but had shown a distinct slowing off in recent years. Karl Pearson had shown that the slowing off of the decline since 1919 had coincided with the period of greatest antituberculosis activity. Dr. Greenwood expressed his agreement with the views of both Dr. Collis and Dr. Willoughby, and went on to refer to the war experiences of all countries which emphasised the importance of the nutritional factor. He mentioned the experience of mental hospitals which ordinarily had a phthisis death-rate eight times the normal. This ordinary excess became an extraordinary excess during the period of war rationing and had now become ordinary again. He considered that diet (whether it was a question of vitamins, fats, or calories) was of the highest importance.

After the four invited speeches, Dr. H. SCURFIELD (M.O.H., Sheffield, 1904–21) distributed the following chart illustrative of the improvement in the phthisis mortality-rate among the Sheffield grinders:—

City of Sheffield: Mortality of Grinders.

	Quenquennia.	
	1909–13.	1923–27.
Deaths, all causes	115	91
Deaths, respiratory tuberculosis	58	33
Percentage	51	37
Average age at death	49	53

He expressed the opinion that the two main factors at work in contributing to this result were the exclusion of open cases of tuberculosis from the grinding "hulls" by the activities of the tuberculosis dispensary and the introduction of improved regulations for preventing the inhalation of the sandstone dust. He further thought it was a pity that anthracosis and siderosis were still retained in the text-books as names of dust diseases of the lungs, as there was no evidence that either coal dust or iron dust per se produced diseases of the lungs, and coal dust even seemed to be an actual preventive of pulmonary tuberculosis.

Time did not permit of general discussion.

OPHTHALMOLOGICAL SOCIETY.

ANNUAL CONGRESS.

THE Annual Congress of the Ophthalmological Society of the United Kingdom was held at the house of the Royal Society of Medicine and the clinical meeting at Moorfields Eye Hospital, City-road. The chair was occupied by Mr. C. HOWARD USHER (Aberdeen), the President, who gave an address on

Relationships between Animals' Eyes and Human Ophthalmology.

It was significant, he said, that at the present time there was no original work on diseases of the eyes in animals by a British author, with the exception

of Wardrop's "Diseases of the Eye of the Horse," 1819. Yet ophthalmic surgery was associated in several ways with the eyes of animals, and the eye of the pig was used for teaching purposes; the transplantation of cornea, or substitution of clear cornea from a rabbit's eye for an opaque portion of human cornea, was an instance of the direct use of animals' eyes for human surgery. He referred to the studies on albinism in man which were conducted by Karl Pearson and Nettleship, with whom the speaker was associated. Since opportunities of examining human albinos were very limited, albinotic eyes had been examined in the dog, horse, rabbit, guinea-pig, mouse, bird, &c. Only two birds among those examined were found to have eyes completely devoid of pigment; one a blackbird whose plumage was all white, the other a greenfinch which had patches of canary yellow on its white plumage. A bird with only pure white feathers might have a red pupil and no ocular pigment, or a red pupil and only a small quantity of ocular pigment. It seemed strange that some of the birds' eyes should contain pigment in the pecten when there was no pigment in any other mesoblastic structure of the eye, as the speaker believed that the pecten was wholly derived from mesoblast. But Bernd found an ectodermal origin, and the major portion of the embryonic pecten on the seventh day was of ectodermal origin, the mesoderm forming a relatively inconspicuous part of it. Miss I. Mann and others had confirmed the two-fold origin of the pecten.

Mr. Usher then went on to refer to the iris colour in winter-white animals, and asked whether there was a seasonal variation in the colour of the iris of animals which changed the colour of their summer coats to white in winter. A number of observations seemed to show that the iris of the mountain hare had less pigment in winter than in summer, though it was difficult to be certain, as this iris had no constant shade of brown in a number of the animals examined. Other series of animals examined did not show seasonal colour changes in the iris. Mr. Usher went on to discuss the help that the study of animals' eyes could afford in regard to heredity. Human pedigrees were much more difficult to work out than were the pedigrees of animals; also the control of matings and the difficulty of obtaining post-mortem examinations were obstacles on the human side. The work now being carried on in this comparative way was likely to be of much value, and to serve a number of useful purposes.

Mr. E. TREACHER COLLINS read a paper entitled

Notes on the Natural History of Retinal Neoplasms.

The conclusions at which he had arrived, on the very elaborate data which he laid before the meeting, were briefly as follows:—

1. At Moorfields Ophthalmic Hospital there had been no evidence, during the past 53 years, of any increase in the number of cases of retinal glioma. 2. Retinal glioma was limited to the very early years of life, as it arose from cells which became highly specialised and soon lost all the capacity they might have had for reproduction. A further point was that this tissue did not contain "mother cells." 3. Cells in metastatic growths of retinal glioma sometimes underwent an increase in size and an alteration in shape, due to a change in their environment, the chief alteration consisting in an increased blood-supply, the blood-vessels in the primary growth being only terminal vessels. 4. The uveal tract when invaded by retinal glioma reacted by forming fibrous tissue, contraction of which might cause shrinkage of the growth. When the ciliary body was invaded the supply of intra-ocular nutrient fluid was cut off, and the loss of this, with the contraction of the newly-formed fibrous tissue, caused the eyeball to shrink. 5. Retinal gliomata were growths of the neural epiblast, and in their mode of dissemination they resembled carcinomata rather than sarcomata. It was more frequent for them to spread by centrifugal permeation along lymphatic spaces than as emboli in vascular channels. For this reason secondary growths were more frequent in the vicinity of the eye than in the internal organs. 6. The blood-vessels of the retina, its only mesoblastic constituent, might certainly be the seat of origin of capillary angiomata, possibly also of angiosarcomata. It was necessary, however, to collect more evidence concerning primary retinal malignant growths commencing after middle life before this could be regarded as proved.

Lieut.-Colonel H. SMITH said it had frequently been asserted that malignant disease was not as frequent among vegetarian people in the East as among meat-eating Westerns, but as one who had had a large experience in both regions he could assert that this was untrue. Many of those who made such statements had only a limited experience in one civil hospital.

Mr. COLLINS, in reply, said glioma could not be attributed to diet, as two-thirds of the cases started before birth.

Lieut.-Colonel SMITH read a paper on the

Early State of Cataract and its Diagnosis.

He said that in Europe cataract development in any individual was spread over years, but in India it matured much more rapidly. He did not think any ophthalmologist could say with certainty what was the cause of senile cataract. To explain cases in India, the glare of the sun had been advanced, but in Burma, where the sun's glare was not less, cataract was not very prevalent. Some said the cause was starvation, but in Punjab where it was common the people were not on the verge of starvation. The idea probably arose from the fact that the Indian's religion precluded the eating of much meat. The least healthy people in India were the overfed denizens of towns, and they also were the shortest lived. In India there was much diabetes after middle life, but it did not seem to exert much influence on the lens. With regard to the probable proximal cause of cataract, the lens had no blood or lymph cells, and so had to live on a specially metabolised pabulum, which probably reached it through the aqueous, which was no doubt also the channel of exit for waste products. In 1910 he had a patient with a thin nebula on each cornea; she had loss of transparency of the lenses and said her vision had become reduced before the nebulæ came; distant vision was less than half normal. He gave her a subconjunctival injection of cyanide of mercury in both eyes. In a month the distant vision was as good as 35 years ago. Since then he had used the treatment in many cases. He did not try it in cases which had definite central dead tissue. He found that in almost every case with vision 6/12 or better the intense hyperæmia re-established vision at 6/6 in three weeks. Cases with a distant vision of 6/15 recovered vision less often, and when vision was less than 6/15, though recovery of vision was great, it was only temporary. He hoped that practitioners would in the future more frequently realise that failing distant vision in people over 50 years of age, with no other complication, was an indication of the early stage of cataract, that at this stage it was curable, and that such cases should be sent to be dealt with by the ophthalmologist. Until, however, the medical schools took up the question the position would probably be little improved.

Mr. A. F. MACCALLAN said he did not think any drug influenced any lenticular opacity. He felt certain that focal sepsis played an important, perhaps the chief, part in the causation of cataract, hence instead of injecting drugs, the sepsis should be sought for and dealt with.

Sir JOHN PARSONS spoke of the danger of injecting cyanide of mercury. He thought a more exhaustive investigation of diet in these cases might usefully be carried out. The greatest advance on the subject of the chemistry of the lens was that made by the work of Miss Dorothy Adams, who found in it glutathione. Two factors were probably concerned in the causation of cataract, one of which was very likely to be light, but this did not act unless the other factor was present too.

Mr. E. WOLFF read a paper by himself and Mr. F. DAVIES on Fragmentation of the Retinal Blood Stream.

(To be continued.)

Reviews and Notices of Books.

BRONCHOSCOPY AND ESOPHAGOSCOPY.

A Manual of Peroral Endoscopy and Laryngeal Surgery. Second edition. By CHEVALIER JACKSON, M.D., Sc.D., LL.D., F.A.C.S., Professor of Bronchoscopy and Esophagoscopy, Graduate School of Medicine, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1927. Pp. 457. 36*s*.

THE first edition of this notable book was reviewed in our columns five years ago. The present edition follows the same lines, but has been enlarged and the excellent series of illustrations has received many welcome additions. In the first chapter the instrumentarium is described; of endoscopes, only those with distal illumination are used or mentioned. Many ingenious forceps for particular purposes are shown, such as those designed to hold staples, to bend wires, and to close open safety-pins; of especial interest are the rotation-forceps furnished with points which permit version of a foreign body into position for safe extraction, and the Tucker tack- and pin-forceps, which throws the shaft of the pin into line with the axis of the endoscope. In Prof. Jackson's Bronchoscopic Clinic general anæsthesia is never used for purely endoscopic procedures, but he concedes that it is perhaps safer for the beginner in his early cases of œsophagoscopy to have the patient relaxed by an ether anæsthesia; local anæsthesia is needless for œsophagoscopy, and if used at all should be limited to the laryngopharynx, for the œsophagus is without sensation. He lays down two postulates: that cocaine should not be used on children under 10 years of age, and that a dyspnœic patient should never be given a general anæsthetic; and he adds a third, that total abolition of the cough-reflex, either by general or local anæsthesia, should be for short periods only. In his clinic children receive no local nor general anæsthetic, nor sedative, for laryngoscopy or œsophagoscopy, but older children have a preliminary dose of morphia or sodium bromide before bronchoscopy. For laryngeal operations and for bronchoscopy, adults are given a preliminary injection of morphia and atropine, or of morphia and scopolamine, and 10 per cent. cocaine is applied to both superior laryngeal nerves on cotton-wool swabs; later, 20 per cent. cocaine may be applied through the endoscope if necessary.

It is well to remember that Prof. Jackson and his colleagues have a very large experience in this work, and the advantage of a team of well-trained assistants; the laryngologist with only occasional experience in bronchoscopy can hardly expect to be able to remove a difficult foreign body from the bronchus of a frightened child without the aid of sedative or anæsthetic. In the treatment of disease of the upper air- and food-passages by endoscopy, where repeated instrumentation is required, it is an enormous advantage to acquire sufficient skill to dispense with anæsthetics; it is unfortunate that practice on dogs, recommended by Prof. Jackson, and harmless to the animals, is not permissible in this country. A large part of the book is occupied by foreign-body problems, the solutions of which are most ingenious and will be of great value to any confronted by these sometimes very difficult cases. In the treatment of disease the author is, naturally, less exact, for the subject is in its infancy; he makes the point, with which most physicians will nowadays agree, that cases of bronchiectasis should be examined endoscopically with a view to determining the cause, which may be foreign body or bronchial stenosis, and therefore amenable to local treatment; in addition, considerable benefit has resulted from endobronchial lavage and injections. He claims that many lives have been saved by bronchoscopic aspiration in cases where the bronchi are occluded by viscid or excessive secretion, a condition which he rather clumsily terms "autodrownage." The warning given that the bronchoscopist is likely to see things, metaphorically as well as actually, narrowly through a small tube, cannot of course be applied to Prof. Jackson himself, but it is natural that he should tend to an endoscopic point of view. Thus he states that a good percentage of cures have been obtained in asthma by bronchoscopic injection of cocaine and adrenalin, without considering that these drugs can be brought into contact with the bronchial mucosa by means of a good nebuliser; he mentions the use of lipiodol for pneumonography only by bronchoscopic injection, and omits the fact that a more even mapping of the bronchial tree can be obtained by the introduction of lipiodol into the larynx or through the crico-thyroid space without bronchoscopy; and, finally, he entirely ignores the removal of innocent tumours of the vocal cords by the indirect method. A short chapter on gastroscopy includes the relation of a very remarkable case in which a safety-pin impacted in the pylorus of an infant aged 11 months was removed by gastroscopy without general or local anæsthesia. The final chapters, dealing with stenosis and with tracheotomy, are not strictly relevant to the subject of endoscopy.

This book, written by an acknowledged master of his subject, will be of the greatest value and interest to all who practise peroral endoscopy.

CENTRAL NERVOUS SYSTEM.

Examination of the Central Nervous System. By DONALD CORE, M.D. Manch., F.R.C.P. Lond., Hon. Assistant Physician, Manchester Royal Infirmary. Edinburgh: E. and S. Livingstone. 1928. Pp. 248. 8*s*. 6*d*.

Dr. Donald Core's conveniently small vade-mecum is intended for the medical student who is training in neurology. That such a book is desirable or necessary is proof of the attention given in these days to the subject, now no longer relegated to the background of medicine. It covers the examination of the motor and sensory systems, the cranial nerves, speech, and the mental state of the examinee. An account of blood pressure and cerebro-spinal fluid investigation and of electrical reactions is included, yet the peripheral nervous system is ignored except for incidental allusion. There are a few diagrams, some at least of which are distinctly unimportant; for neurological diagnosis a knowledge of neuro-anatomy is essential, and some illustrations elucidating anatomical matters in routine examination would have been useful. In respect of actual technique the descriptions are sound and reliable, and appropriately concise; we have observed but a few to which minor exception might be taken. The attempts made to differentiate types of involuntary movement—e.g., "clonic muscle movements" (sic) from both "chorea" and "myoclonus"—can be carried out in theory vastly more easily than by the bedside. It is highly questionable if true flexibilitas cerea occurs in the Parkinsonian syndrome. Under supranuclear lesions of the oculomotor group no reference is made to conjugate paralysis of vertical movements; the symptom-complex of paralysis of the ocular components of the cervical sympathetic is not given in its entirety. These and other mild blemishes might with advantage be removed in another edition.

MENTAL HYGIENE.

By DANIEL WOLFORD LA RUE, Ph.D. New York: Macmillan Company. 1927. Pp. 443. 10*s*.

THIS little book is intended to appeal to pupil teachers, and aims at training them in healthy habits of mind so that they may impart these, by example even more than by precept, to their pupils. It is divided into four sections, of which the first deals with personality and the mind generally, the second with pathological manifestations, the third with special aspects of mental hygiene and social adaptation, while the fourth is concerned with child study and the application of the principles advocated in the teaching profession. The last section is by far the best, being ground upon which the author has evidently

practical knowledge; he emphasises the importance of the emotional life of the child in education, and gives sensible and valuable advice on the handling of such problems as that of the nervous, timid, irritable, or shut-in type of child. The exercises suggested are numerous and varied, well calculated to induce the pupil teacher to think out for himself the individual and collective problems likely to be met with in his work. For the English reader the book is rather like an excellent pill, its sound content spoilt by the sugar-coating of sentiment.

MOLECULAR PHYSICS

and the Electrical Theory of Matter. Fourth edition. By JAMES ARNOLD CROWTHER, M.A., Sc.D., F.Inst.P., Professor of Physics in the University of Reading. London: J. and A. Churchill. 1927. Pp. 202. 7*s.* 6*d.*

Prof. Crowther's book has now reached its fourth edition and if the author is willing to continue his work on it, so that it keeps abreast of discovery, it is safe to say that there will be many more. It is an excellent book, full of information indicating clearly where we are on sure experimental ground and where we enter the region of speculation. The author has a vigorous and attractive style, not devoid of humour. Readers who skip the mathematics will find that much remains for them.

TO-DAY AND TO-MORROW.

Cain; or the Future of Crime. By GEORGE GODWIN. London: Kegan Paul, Trench, Trübner, and Co. 1928. Pp. 108. 2*s.* 6*d.*

Hermes; or the Future of Chemistry. By T. W. JONES, F.C.S. Pp. 88. 2*s.* 6*d.* Same publisher.

WE have received two more volumes of the well-known "To-day and To-morrow" series, which have both been written under the same difficulty—namely, that no possible condensation can give any outline of the subject which would not seem to some readers incomplete, and to others unnecessarily detailed. Both authors have met the difficulty bravely.

Mr. Godwin starts unluckily by the wholesale assumption that the story of the Jukes Family as usually handed down cannot be criticised, and follows with an attempt to define criminality which he himself concludes cannot be done. All, however, will agree with him that the cure of the criminal has little direct relation to punishment, and at this point we have a valuable section on the varieties of punishment and the position of irreclaimables. The gist of his plea is that where cure is possible, a responsibility lies with society to provide the means, but that where cure is impossible, removal of the stumbling-block to racial and international progress is justified. Surely we shall advance in our ability to diagnose the two classes as separate, but while our knowledge is accumulating, the course proposed must lead to fierce discussion. Interesting sections deal with the petty and the juvenile offender and juvenile courts, and the author notes with special reprobation the leniency of magistrates towards sexual offences, and criticises the short sentence as futile to arrest crime in many circumstances where it has been employed. The little book closes with some suggestive thoughts concerning the criminal trial of the future and an outspoken summarising of the qualifications necessary to the making of a good judge, while the author provides a solution for some of the problems in the following words: "The renunciation of the desire for revenge, and with it all those barbarous crimes which to-day are done in the name of the community . . . of the soft sentiment that holds our hands from drastic remedies when drastic remedies are necessary . . . the exercise of intelligence upon the problem, that has hitherto been the preserve of the judge and the gaoler."

If Mr. Godwin had a difficult task in outlining the future of crime in a few pages, Mr. Jones had an impossible one in the attempt to do the same for chemistry in "Hermes," when we consider the range of knowledge that is implied in the title. It may be said that the range cannot possibly be greater than that of the contributors to the series who provided those brilliant essays, "Science and the Future" and "The Future of Science," but when one branch of science is in consideration, detailed information is called for, and when that branch itself makes endless ramifications, how is the amount of that detail to be defined. The author of "Hermes" tackles the situation logically, and his small book is packed with facts presented in an intelligible manner and as far as possible in an orderly sequence. The closing pages, which discuss death as a biochemical phenomenon, pay a valuable tribute to the result of the modern union between chemistry and pathology, while he prophesies, as is now becoming the habit of our philosophers, the accomplishment of some complete revolution in our treatment of disease. He finds that the establishment of the germ origin of much disease has led medicine into direct attack upon the causal entities by the introduction of various preparations, whereas the scientific method of dealing with the situation would be to assist the organism of its own accord to set its parts in order. Briefly, the problem before the biochemist, in his relation to the future of therapeutics, will be to discover the excitants that will stimulate the diseased body to produce its antitoxin when disabled by disease. Chemistry of such an order would open up an astonishing vista of possibilities to the clinician and, even if such chemistry is verily in the future, it may be pointed out that a beginning has been made.

New Inventions.

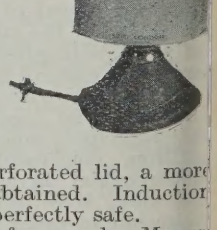
ARNBERG'S ELECTRO-MEDICAL APPARATUS

THIS apparatus, the design of a Swedish engineer, provides alternating current of what is claimed to be pure sine wave form at 20 cycles per second varying from about 5 to 25 milliampères and 20 to 70 volts. By a special device the milliampères passing through the patient do not depend on the resistance of the tissues, thus unpleasant shocks are avoided when a patient of unusually low resistance is being treated. The apparatus appears to be rather bulky considering the power supplied to the patient, and is expensive; whether the other advantages it possesses will compensate for their disadvantages can, of course, only be decided by actual use of the apparatus.

The apparatus can be inspected and tested at 20, Park-crescent, London, W., where Mr. B. Cederin will demonstrate its claims to medical practitioners or those in charge of electrical departments, by appointment between noon and 1 P.M., or between 3 P.M. and 4 P.M.

AN IMPROVED INHALER.

THE accompanying illustration shows an inhaler I have designed, which has many advantages over the usual type used for the open method. It consists of an oval metal container with a hinged perforated lid. The bottom has a funnel to which any standard face-piece may be fitted. This funnel is continued up into the inhaler and forms a trap into which any liquid anæsthetic will collect, thus preventing it from falling on the patient's face. A removable perforated tray is provided in which to place gauze or sponges; these are saturated with ether or a C and E mixture, or they may be sprayed with ethyl chloride. By moving the hand over the surface of the perforated lid, a more concentrated vapour can be obtained. Induction of anæsthesia is very rapid and perfectly safe.



This inhaler has been made for me by Messrs. A. Charles King, Ltd., of 34, Devonshire-street, W. 1.

CHARLES W. BROOK, M.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, APRIL 28, 1928.

LIVER IN PERNICIOUS ANÆMIA.

WE publish this week an article from the Edinburgh school on the treatment of pernicious anæmia with liver and liver extracts, along with a series of reports contributed at our request by a representative group of clinicians. Taken together these articles form an overwhelming mass of evidence, confirming what has been the general experience throughout the world since this method of treatment was introduced by G. R. MINOT and W. P. MURPHY, of Boston, U.S.A., that in liver, whether taken whole or in the form of some suitable extract, there exists a specific remedy for this hitherto incurable disease. The introduction of the Minot-Murphy treatment ranks as one of the most sensational episodes in the history of medicine. Since pernicious or primary anæmia was separated from the general mass of anæmias, by the work first of ADDISON and later of BIERMER and EHRLICH, it has been recognised as an entity possessing singularly few points of resemblance to any other condition. The high colour-index of the blood, the presence in it of abnormally large red cells, the great excess of bilirubin in the serum, and the absence of free hydrochloric acid from the stomach contents are cardinal factors in the diagnosis, and many attempts have been made to arrive at some comprehensive conception which would explain the association of these factors in a characteristic symptom-complex. The presence of bilirubin in the serum and of an excess of its derivatives in the urine led EHRLICH to postulate excessive hæmolysis as the underlying cause, and under his influence research was directed towards the identification of a hæmolytic agent. Abnormal fats and their split-products were implicated by one school of workers; by another, the presence in the intestinal canal of abnormal organisms, whether hæmolytic streptococci or some strain of *B. welchii*. Some workers, while conceding hæmolysis as the underlying factor in the anæmia, denied the existence of a hæmolytic toxin and attributed the anæmia to excessive blood destruction on the part of the reticulo-endothelial system. This school of thought was in turn divided against itself, some members regarding the primary disturbance as being located in the reticulo-endothelial system, while others believed the bone-marrow to be at fault in producing red cells so abnormal as to be destroyed, after liberation into the circulation, by a reticulo-endothelial system which failed to recognise abnormal red cells as better than none at all. In pursuance of these views the surgical removal of the spleen—the largest available mass of reticulo-endothelial tissue—enjoyed, for a time, a vogue in the treatment of pernicious anæmia. The results attained were on a level with those of the various other forms of treatment which preceded the Minot-Murphy epoch. All the theories of ætiology agreed in regarding excessive hæmolysis as the underlying factor of the anæmia and all the evidence seemed to point in that direction until the publication of the work of G. H. WHIPPLE. Whether it will now be necessary to jettison the hæmolytic theory altogether does not yet appear. In any case, whatever views they held of its causation, all have united in the past in regarding pernicious anæmia as a condition which progressed, with remissions, inexorably to a fatal issue. How short was the expectation of life once the disease was established is well shown in the records of patients treated at the London Hospital (see p. 872) before the days of liver. There now exists an equal unanimity that in liver we possess a remedy which will rapidly restore to normal the blood picture of the patient with pernicious anæmia, although how long the improvement will be maintained and whether or not patients will continuously respond to it is not yet known. The indications at present appear to be that the blood count will remain normal so long as liver is taken, and that should it fall it can rapidly be brought up again by increasing the dose.

Two years ago there would have been few medical men credulous enough to believe in the possibility of so simple and yet so specific a cure for a hopeless condition. To-day the consensus of opinion as to the efficacy of the treatment is complete, and there is a natural desire to put it alongside of salvarsan and insulin as a triumph of experimental medicine. The case for so doing is not quite clear. It is true that the treatment was inaugurated by MINOT and his co-workers largely as the result of experimental work upon which WHIPPLE and his associates had been engaged since 1921, but there are other tangled strands to untie. Some years ago MCCOLLUM, BENEDICT, MENDEL, and others showed that in most young animals an acute anæmia, largely due to iron deficiency, can be produced by prolonged milk-feeding. In young herbivores they found that a supply of iron did not remedy this anæmia, but cure could be brought about by administering the vitamin E normally present in vegetable food. Other workers laid stress on vitamin D; GIBSON and HOWARD (1923) wrote: "Our experiments would tend to confirm those of Whipple and his associates that in experimental hæmorrhagic anæmia in dogs, blood regeneration is hastened on a diet containing meat, liver, and other iron-rich foods." Liver was at first regarded merely as a form of meat, and it was only recognised later that meat, such as liver and kidney rich in nucleo-proteins, was more effective than simple muscle. At this stage MINOT and MURPHY applied a high-protein high-vitamin diet to the treatment of pernicious anæmia, and liver soon became recognised as much more effective than any other type of meat, though it may be mentioned that MCCANN has just reported almost as good results with kidney. So far, there seems no reason why experimental medicine should not claim a triumph. As knowledge grew, however, it became more and more doubtful if liver had a specific effect upon any type of anæmia other than pernicious. Most of the experimental work was performed on animals suffering from secondary anæmia, the result of bleeding; the treatment should then be of use in the secondary anæmias met with in medical practice. It is already obvious that any effect it may have in these is in no way comparable to that seen in anæmia of the pernicious type; so specific is the response that the condition has even been diagnosed upon the response to treatment alone. On the other hand, such effects as have been produced by liver in the treatment of secondary anæmias might have been attained by any form of high-protein diet; it is no new conception that anæmic patients require "feeding up" on "butcher's meat."

The results set out in our present issue serve to confirm the conception of Addisonian anæmia as a peculiar entity, and of liver as a unique agent for altering its course and, incidentally, for investigating its nature. Enlargement of our ideas of ætiology seems certain to result. One of the effects of giving liver is a transient but very great increase in the percentage of reticulated red cells in the circulation; that the serum bilirubin falls rapidly to normal is also obvious from the appearance of the patient The increase of the reticulocytes would at first sight seem to indicate an increased activity on the part of the bone-marrow, which is known to be abnormally active in this condition. The defect in the bone-marrow seems to be not so much a failure of blood formation as a failure to bring the red cells to maturity, the immature cells being destroyed on liberation into the blood stream. On this view liver might be regarded as what used to be known as an "alterative" so far as the bone-marrow is concerned, and the diminution of the serum bilirubin on treatment would fall in with this view. ASHBY and others have, however, offered good grounds for believing that no toxic hæmolytic agent is active in this condition, and some would go further and rule out hæmolysis altogether from the conception of pernicious anæmia. By such, the increase of the serum bilirubin and the deposition of iron in the tissues, hitherto regarded as conclusive proofs of hæmolysis, are attributed to inability on the part of the blood-forming organs to use these substances rather than as evidence of blood destruction. This point awaits further investigation, and the time has not yet come to discard the older view of pernicious anæmia as essentially a hæmolytic condition, though not of necessity due to a hæmolytic toxin.

How such a simple and specific treatment for so well-recognised a condition should have escaped detection for so long is amazing. Liver forms an article of diet among the peoples of the world; pernicious anæmia is a widespread disease; is it possible that no one before Drs. MINOT and MURPHY ever brought the patient and the cure together? Search in the backwaters of medical history may provide an answer. A few instances of the successful therapeutic use of liver in the past have come to light and probably more will be forthcoming. Thus NÄGELI reports the appearance of nucleated red cells and the improvement of the blood count in a patient who consumed enormous quantities of *Blutwurst*. NÄGELI attributed this to the blood in the sausage, but it may have been due to the liver which usually enters into the composition of this delicacy. In some parts of this country black pudding enjoys a vogue in the treatment of anæmia; presumably it was given for the sake of the blood it contained, and the tendency of late has been for its replacement by more elegant preparations of hæmoglobin. Black pudding also contains liver. From Australia comes the report we published a week or two ago of a Chinese herbalist who restored to perfect health a case of known pernicious anæmia by administering a powder consisting of the dried liver of carnivorous crows. It would be instructive to find out to what extent this preparation is used in the treatment of anæmia in the East. The relief of sprue by liver has long been recognised. It is, in fact, hardly possible to determine, as yet, whether this latest addition to specific therapy should be regarded as a triumph for the experimentalists or the empiricists. There can, however, be no doubt as to whom the credit for the inauguration of the treatment is due, and the world owes very real gratitude to WHIPPLE, MINOT, MURPHY, and their co-workers.

STERILISATION AND MENTAL DISEASE.

A GENERATION ago this subject was mentioned with bated breath. To-day it is not only openly discussed, but there have been several occasions during the past few years when it has been brought prominently before the general public at home. Their opinion has been so adverse to sterilisation that there is no immediate prospect of the passing of any legislative proposals, although such action is attracting the serious attention of public bodies and of persons interested in social reform. In matters of this kind new countries are apt to act with somewhat less deliberation than are those of older standing. So long ago as 1907 the State of Indiana passed a sterilisation law, and within 15 years 14 other of the United States had followed suit. It is not without interest to note that subsequently five of these States declared the law to be unconstitutional and invalid, another repealed it, in four others it became practically a dead letter, and in 1922 there were only two in which it was made use of to any considerable extent. The Legislature of Alberta, Canada, has just passed a Bill providing for the sterilisation of persons whom it is proposed to release from mental hospitals. This Bill applies to the recovered insane as well as to mental defectives, and is to a large extent optional. Thus, in the case of the insane the operation is not to be performed without the patient's consent. In cases where the board of examiners are of the opinion that the patient is not capable of giving such consent—and such will presumably be mental defectives—consent is required from the husband or wife, parent or guardian, or in their absence from the appropriate Minister of the Province.

The reason for this increasing attention is not far to seek. Inheritance plays an important, if not the chief, part in the causation of mental disease; there are indications that such disease is becoming more prevalent; the cost of establishing and maintaining institutions for persons so suffering has become a serious item of national expenditure. It is with the hope of solving these problems that sterilisation is advocated. At the same time the subject is clearly one which has many aspects and which presents many difficulties. There are considerations of State and religion. To what extent, for instance, is the State justified in mutilating a person who has committed no breach of the law? To what extent do religious tenets sanction or oppose such an interference with life? Although we propose to confine our consideration of the subject to its eugenic and economic aspects it is clear that both law and theology might have much to say concerning it. The advocates of sterilisation claim that it would accomplish two things. First, it would permit of many persons who are now resident in institutions being discharged and so reduce their cost to the State. Secondly, by preventing the propagation of such persons it would greatly diminish the incidence of mental disease. Hitherto the proposals in this country have been concerned almost entirely with mental defectives; the recent Canadian measure, as we have mentioned, applies not only to these, but also to the recovered insane. A little consideration will show that the two classes stand upon very different footings, and that a method might well be appropriate to the one but unsuitable to the other. Thus, in the great majority of persons who have recovered from an attack of mental disorder, there is no economic issue; the problem is purely one of eugenics. There is no question of keeping them under care, most of them are able to return, and do

return, to remunerative work. But they may, and do, beget offspring, and it is considered that such offspring are often similarly affected with mental disorder. It is probable that this view will meet with general acceptance. It also seems likely that certain dangers which it is held would attend the sterilisation of the mentally defective would not apply to the class we are now considering. But if the procedure is to be compulsory there arises the practical difficulty of deciding where to draw the line. The same hereditary influences may be at work in obsessional and anxiety states, "shell-shock," hysteria, emotional instability, and the like, as in paranoia, manic-depressive, and other forms of legal insanity. This would appear to render the selection of cases for compulsory sterilisation not only an invidious but an almost impossible task. The Canadian measure avoids this difficulty by making the operation subject to the consent of the patient, but we are not aware that any legal sanction is needed to enable a person to avoid procreation if he or she wishes to do so, either by sterilisation or otherwise.

In this country sterilisation has hitherto been proposed chiefly, if not entirely, in the case of the mentally defective, and the reasons have been economic as well as eugenic. It must be remembered, however, that mental defectives are, by statutory definition, persons incapable of managing themselves and their affairs without care, supervision or control, and although there are undoubtedly many patients who do not need institutional care it is a moot point whether the release of thousands from institutions, where for the most part they lead useful, regulated, and not unhappy lives, would be attended by any financial saving. Many authorities consider that it would not. Social workers are also practically unanimously of the opinion that there would be very considerable danger of the release of sterilised feebleminded and unstable young women resulting in an increase of promiscuous sexual intercourse with the consequent spread of venereal disease. Although there are, no doubt, individual cases in which sterilisation might be an appropriate procedure, these opinions are deserving of very serious consideration in regard to any proposals for the wholesale sterilisation of mental defectives. With regard to the eugenic aspect it is generally admitted that inheritance plays the chief part in the production of mental defect. It is also an unfortunate fact that many cases have been recorded of defective parents producing defective offspring. In spite of these facts, however, it is open to question whether the sterilisation of defectives would have any appreciable effect upon the incidence of mental deficiency. The explanation of this paradox is that although the majority of mental defectives are the progeny of neuropathic stock, the proportion who are the offspring of an actually defective parent—that is to say, of a person who would have been liable to sterilisation—is, in relation to the whole, an exceedingly small one. Within the past few years the whole question has been considered very fully and carefully by the medical committee and council of the Central Association for Mental Welfare. This association is the chief non-official body in the country dealing with defectives; it embraces practically all the leading medical and lay authorities on the subject, and during a period of ten years 34,000 cases of mental abnormality passed through its hands. The Council arrived at the conclusion that whilst sterilisation might be appropriate in certain particular cases, its general adoption would have little preventive effect, that the freedom accompanying it would be attended with positive harm to the defectives themselves, that it would not result in any financial saving—that, in short, the procedure would benefit neither the defectives nor the community. Coming from an authoritative source, these opinions cannot be lightly set aside.

ULCERATIVE COLITIS.

FACED with an acute illness in which the patient passes frequent stools containing blood and mucus, few practitioners would hesitate to diagnose dysentery, and to attribute the condition to some specific organism. The fact that bacteriologists now recognise that it may be caused by several races of bacteria, differing from Shiga's bacillus in their cultural and serological reactions, has done little to change clinical conceptions of the disease. In this country, however, most medical men have few opportunities for observing the acute stage, for although this is very common in the tropics and sub-tropics, it is rarely seen in the temperate zones except where many people are crowded together, as in armies or institutions, and the virus is introduced by a carrier. Subacute infection, on the other hand, may well be more prevalent than is generally supposed. In the first place it may be due to the *Entamœba histolytica*, which WARRINGTON YORKE and others have shown to be endemic in England, affecting up to 10 per cent. of the population. But even apart from this and other specific causes of intestinal ulceration, such as tubercle, syphilis, and gonorrhœa, there is a large group of chronic cases for which the dysentery bacilli has been held responsible. They are characterised by the presence of blood and mucus in the stools; their onset is insidious; their course, though chronic, is often interrupted by exacerbations; and they are labelled "ulcerative colitis." It was to this important group that the Harveian Society gave its attention at a meeting last week, which we report on page 857.

The belief that dysentery bacilli, especially of the Flexner type, commonly cause chronic infections of this kind was widely held in the first few years after the late war, and many physicians were led to administer antidysenteric serum in cases of ulcerative colitis. The results of this attempt at specific remedy were disappointing and its use has now been largely abandoned. Rational therapy, however, must depend upon treatment of the cause, and this failure continues to inspire fresh efforts towards the discovery of the underlying factor, bacterial or otherwise. Bacteriologists, searching in vain in ulcerative colitis for the bacilli which are readily found in acute dysentery, have described organisms allied to the common colon bacillus which they say are liable to become pathogenic, and a number of "pseudo-dysentery" bacilli with varying biochemical reactions have been brought forward as possible causes. Whilst the evidence for these is not convincing, the claims made for other intestinal inhabitants, such as the anaerobic spore-forming bacilli and the streptococci, are no more substantial. The diplococcus of Bargen, a recent claimant, which has been isolated not only from the fæces, but from material removed from the cleansed surface of ulcers through a sigmoidoscope, seems to be identical with the enterococcus; and the latter, though tenacious of life—it even stands momentary boiling—and reported periodically as a cause of disease, has no great pathogenicity. Perhaps, like so many intestinal bacteria, it is a secondary invader of damaged tissue, but its responsibility for setting up ulcerative colitis cannot yet be accepted.

These indefinite results have led to the exploration of other possibilities in the search for a primary cause. LARIMORE, for instance, regards an avitaminosis as the basis of chronic ulcerative colitis, and MCCARRISON in 1921 demonstrated injury to the intestinal mucosa in animals deprived of vitamins. That chemical substances may play a part in ulceration is well known; physicians who remember the days before the Wassermann reaction made it possible to establish the diagnosis of syphilis will recall the severe ulcerations of the colon produced by mercurial saturation of patients who suffered from obscure affections of the nervous system and other chronic diseases. It is possible, therefore, that ulcerative colitis may be caused not only by lack of vitamins, but also by chemical substances, of composition at present unknown, which damage the bowel, their lesions being infected and kept active by the otherwise harmless intestinal flora. In tropical countries the white man has learned to exercise the greatest care to avoid the use of contaminated and tainted food, for a lapse may be followed by swift and severe consequences, but in England and temperate climates a lower standard of hygiene is customary and the food often includes game that is high and milk that is stale, whilst meat by no means above suspicion is included in stews and made-up dishes. It is possible that such frequent insults to the intestinal mucous membrane set up lesions in the lower colon where the intestinal contents lodge in the intervals between defæcation and where ulcerative colitis usually begins. This is a revival of the old notion of "stercoral ulceration," modified to include chemical as well as mechanical injuries to the bowel wall from its contents.

Annotations.

"Ne quid nimis."

CLUB-FOOT.

FROM the time of Hippocrates club-foot has been well known, and although we cannot be sure that any distinction was made between congenital and acquired deformities, the Father of Medicine described a rational method of treatment for those cases which escaped the fate of death by exposure, as was generally the lot in Greece of the infant born deformed. In another column we publish a paper by Mr. Wilfrid Adams of Bristol in which he describes the course of treatment which he has found successful in 30 cases of club-foot in the new-born which have come under his care. Those who have had the most experience of the treatment of such cases will be the most likely to agree with him and approve of his methods and also will be best able to appreciate the amount of patient perseverance which has been necessary to secure good results. Mr. Adams quite correctly states that no other deformity presents such a record of failures and incomplete cures. When W. J. Little wrote his book on club-foot in 1839 he probably thought that with Stromeyer's introduction of a safe method of tenotomy and the treatment which he described, all club-feet would in future be cured. Yet we find that 89 years after that book appeared, failures and relapses are still reproaching us. The method described by Mr. Adams is essentially that of Stromeyer, or—with the exception of tenotomy—that of Cheselden. In this branch of practice as in so many others, men are often of greater importance than methods, and the more successfully the surgeon can impress his personality on the mother or nurse so as to induce her to take unremitting care of a case of talipes for some years after birth, the better will be his results. If eternal vigilance is a condition of the preservation of liberty as Curran said, it is also a condition of the successful and permanent cure of club-foot. Mr. Adams confesses to a fear of doing too much and turning a club-foot into a flat-foot. We think that this is a baseless fear and agree with Sir Robert Jones and others that over-correction should be aimed at, for the risk of producing any serious disability in this way is trivial and at the worst a foot that is anatomically flat is better than a relapsed club-foot. In some cases, too, it seems that there is no mean, but that for permanence, if the foot is not to be varoid, it must be valgoid, for the middle position is one of unstable equilibrium.

Congenital club-feet are classified by some writers as due either to primary causes affecting the embryo in its earliest stages or to the environment of the fœtus at later stages. Not much is certainly known about this, but to surgeons who have treated many cases of club-foot it is evident that there are some in which the original vice of constitution persists, so that the foot, however thoroughly corrected, tends as growth goes on to reassume the vicious form. Weakness of the overstretched abducting muscles, to which Mr. Adams refers, may be due merely to overstretching or to a more radical tendency in the embryo. There is little doubt that too much was expected of tenotomy for years after Stromeyer's subcutaneous method was made known, and too many surgeons thought that all they had to do was to divide certain tendons. In the method described by Mr. Adams, all the work of correction of varus is done before the tendo Achillis is divided and the subsequent correction of the equinus deformity is comparatively easy. The history of tenotomy is one of isolated successes followed by no permanent advance. No doubt failure to occupy permanently the territory gained by one success was due to lack of cleanliness and to the prevalence of wound infection. The idea that the tight cord of the tendo Achillis might be divided must have occurred to many people and some of them must have seen cases in which tendons accidentally divided or torn had re-united. Among the "cases" described by Little in his book is that of Thomas Inglis, M.D., of Glasgow, who had suffered from what was stated to be talipes equinus congenitus. Before the beginning of his medical studies, Inglis became convinced that the contraction of the tendo Achillis prevented his heel from descending. He communicated a suggestion of tenotomy to the family doctor who discountenanced it. He therefore divided the tendon himself—no doubt by open incision, for there was considerable bleeding. Medical advice was called in and the foot put up in extreme equinus so that the deformity was restored. Fifteen years afterwards the tendon was divided subcutaneously with a most satisfactory result. Thus Inglis might have claimed to be the first surgeon in Great Britain to divide a tendon for the cure of club-foot.

THE ACTIVE SUBSTANCES OF THE THYROID.

FOR some years past, as our readers will remember, Dr. G. Scott Williamson and his colleagues have advanced views on the structure and function of the thyroid which are at variance with those most generally accepted. He regards the thyroid as having a distinctly dual function. On the one hand is the accumulation of colloid in the vesicles which dominate the normal histological picture, on the other the production of a genuine secretion in the adenoid areas of the normal gland and throughout the organ in Graves's disease. The two functions are interchangeable phases in the activity of the normal thyroid epithelium, and tissue in the secreting phase can be distinguished and separated from tissue in the colloid phase by careful examination of slices of many normal glands. Evidence is now produced (*Jour. Path. Bact.*, 1928, xxxi., 255) which seems greatly to strengthen this position. Dr. Williamson, working with Dr. Innes Pearse and Dr. Hilda Cunnington,

found iodine in only 12 out of 200 samples of secreting tissue from normal glands, whereas 100 samples of colloid tissue all yielded iodine in larger or smaller amounts. Moreover, iodine when present in secreting tissue is contained in the cells; the contents of the follicles have none. Similarly all of 20 vesicular goitres contained iodine, and only 11 out of 50 adenoid goitres from untreated primary Graves's disease. Turning next to the biological test for active thyroid substance—the power to accelerate the metamorphosis of tadpoles—they show that secretion tissue is inactive, even when it contains some iodine, and that colloid tissue is active. It is difficult to resist the conclusion that the thyroid is doing two quite different things when it produces colloid (if indeed that substance really originates in the gland) and when it produces secretion, and these observations plainly support the view that Graves's disease is not simply hyperthyroidism. The known active constituent of the ordinary colloid gland is thyroxin which contains iodine and accelerates the metamorphosis of tadpoles; it seems that secretion tissue in the normal gland and in Graves's disease contains no thyroxin. What is curious is that thyroxin increases metabolism and that a raised metabolic rate is one of the fundamental characteristics of Graves's disease. Whether there are two substances which increase metabolism or what other explanation there may be of this apparent difficulty must be left for further inquiry to solve.

THE TREATMENT OF THE PSYCHONEUROSES.

THE Cassel Hospital for functional nervous disorders at Swaylands, Kent, continues its successful work on the psychoneuroses. Its sixth annual report deals with the year 1926, since its practice is to allow a year to elapse before assessing the effect of treatment. 102 new patients were admitted; 70 were well or much improved at the date of the report; 21 were not benefited, and the remaining 11 have died or did not reply to their questionaire. The number of improvements is rising steadily, doubtless because of the experience which the staff have acquired. The reports of the Cassel Hospital form a series of valuable treatises on this branch of psychiatry, and should not be missed by those interested in the minor mental disorders. Dr. T. A. Ross now divides the obsessional group of patients into ruminative and compulsive obsessives, a distinction which has often been admitted but rarely if ever definitely formulated. Obsessions are thoughts or trains of thought from which the patient is unable to free himself, but whereas some of these thoughts are rational, others are not. Continual theological speculation may be undesirable, but it is at least rational; the idea that the hand is gradually turning into a claw is not. The second idea is not a delusion, for the patient is constantly rejecting it, but he very often has to buy it off by performing some compulsive act, which has the quality of a ritual or magical practice designed to avert evil. The difference between the two groups is very important. The ruminative symptom is probably a substitutive idea indicating that some sentimental adjustment is required, or that some effort at adaptation must be made; it is closely allied to an anxiety state and the prognosis is favourable. The compulsive group suffer from a disturbance of a much more primitive layer of the mind, representing a much greater disintegration of the personality, and their prospects are definitely bad. Dr. Ross says that, so far from being a large class, as some writers hold, obsessional patients are rare; he has placed only 12 in the ruminative and six in the compulsive groups since the hospital started. He suggests that many anxiety patients, especially those suffering from phobias of disease, are wrongly classed as obsessional. One of the great virtues of Swaylands is the support which it gives to discharged patients. Of 24 return cases, 17 were much improved or well after their second stay, although the majority only came in for a week or two. A talk over remaining difficulties or old symptoms seems to come more easily the second time, and the feeling that, if the worst should befall, Swaylands is there to help, must keep a number of depressed ex-patients from despair. Against this, of course, is the tendency of a certain number of hysterical patients to regard the place as a refuge from difficulty and to manufacture symptoms to get there. Dr. Ross's views on the incipient case of adolescent insanity are especially important. The hospital has almost given up diagnosing early schizophrenic cases as dementia præcox. A number have got well, and it does not matter much, he thinks, whether these are really hysterical or not. He considers it wiser to call them schizophrenic, treat them if possible, and discharge them if their conduct harms the other patients. They require different handling from the hysteric, for they thrive on a sympathetic method of approach which would make a frank hysteric much worse. Whereas the hysteric benefits from being shown plainly what he is and what he is doing, the schizophrene, according to Dr. Ross, needs to be rather spoilt. This may be because the hysteric has an already integrated personality, whereas the schizophrenic has never reached the stage of "finding himself." Adolescent insanity is admittedly on the increase, and far from being incurable yields very good results to early skilled treatment. The more sparing psychiatrists are with the words "dementia præcox," the greater will be their proportion of rescued schizophrenes.

THE USE OF MERCURY AS A DIURETIC.

Dr. L. Blum and Dr. P. Carlier have just published an account [1] of two cases of œdema and ascites in which the diuretic effect of organic preparations of mercury is shown to be increased if they are preceded by a preliminary course of calcium or ammonium chloride. The first case was that of a man of 62, with alcoholic cirrhosis œdema, gross ascites, and diminished excretion of urine, which a salt-free diet had failed to relieve; the second case was one of cardiac failure in a man of 42, associated with enlargement of the liver, gross œdema and ascites, but no evidence of kidney involvement. In both cases intramuscular injections of 0·5–1·5 c.cm. of neptal were followed by diuresis only if 6 to 12 grs. of calcium or ammonium chloride had been given daily for three to six days beforehand. With this preliminary preparation diuresis was copious and constant; without it the neptal had practically no effect. The authors consider that calcium and ammonium chloride act by producing a slight degree of acidosis which prepares the organism for the diuretic effect of the mercury and make its action much greater. The ideal dose of chloride varies in each case. It sometimes happened that 60 grs. in three days, which was at first sufficient to produce profuse diuresis, had to be increased later to 80 in order to obtain the same effect. Mostly, however, 10 to 20 grs. of salt per day was sufficient. If calcium chloride is used the basic radicle is rapidly excreted in the urine, and if ammonium chloride is used the ammonium is changed into urea in the liver and excreted in this form. The latter salt has certain advantages over the former in that it is less nasty and the taste is less persistent, and it is less likely to cause constipation. On the other hand, since the ammonium is turned into urea, it should not be used if there is extensive liver damage. This combination of chloride and mercury is unnecessary in many cases, which react perfectly to mercury alone, and it is chiefly indicated in cases of alcoholic or cardiac cirrhosis with much ascites. Cardiac and cardiorenal cases with generalised œdema are generally unsuitable for the combined treatment which should only be used if other measures including mercury alone have failed. For the œdema of renal disease these salts are in most cases not to be recommended; while if pyrexia is present calcium and ammonium chloride may be given alone and are often effective, but mercury is contra-indicated.

THE INTELLIGENCE OF DOGS.

THOSE who wish to know what exact observation has made of the sensory and intellectual capacities of domesticated dogs should read a paper in the current number of the *Quarterly Review of Biology* (1928, iii., 1), by Mr. C. J. Warden and Mr. L. H. Warner, of Columbia University. They will probably be surprised to find that the animals come so badly out of the cold arbitrament of experimental psychology. The experiments have to be made with the greatest care; in particular precautions must be taken that the observer cannot indicate by any movement whether the dog is doing, or seems likely to do, rightly or wrongly, in any given test. In this kind of perception dogs are certainly very sharp, which fits in well with their intimate dependence on man as contrasted with the aloofness of a cat; the dog is always quick enough to apprehend the signs and symptoms of approval and disapproval. Excluding this potent source of error, it seems that these animals have little power of discriminating the form of smallish objects or the brightness of lights, though they can by long enough teaching be trained to make fairly fine distinctions. In common with other mammals below the apes and monkeys, they have no sense of colour. Sight seems to be of little help in getting out of difficulties. For example, a dog was trained to open a box by lifting a latch to obtain food; in his absence the box was then turned through 90°, after which he went to the place where the latch had been and pawed about although the latch was plainly in his view. The dog's olfactory sense is admittedly of an order standing very high on the human scale, but even here accurate tests seem to show that his ability to recognise individual human beings by smell has probably been exaggerated, as well as his capacity to follow trails more than a few hours old. Police experts have become very doubtful of the value of a trained dog's recognition of the owner of, for instance, a piece of clothing, and the use of dogs in criminal detection is now forbidden by the Prussian Government. Apart from the fact that, like the cat, he can hear high notes which are beyond the human range, the dog apparently has an auditory capacity not very unlike that of man. But of his power to learn the meaning of words there is a great deal of doubt. The famous dog of Mannheim, so they say, learned reading, writing, and arithmetic from listening to the governess and the children, but "Fellow," trained from puppyhood by Mr. Herbert, of Detroit, to understand the spoken word did not pass very successfully through the tests to which Warden and Warner subjected him; indeed he was wrong about as often as he was right. The inference is that dogs are not nearly as clever as they seem, and that their "intelligence" is mostly derived from their human companion, with whom they have an exceptional power of establishing an emotional nexus.

DEFORMITIES OF THE JAWS.

ORTHODONTICS, though the youngest branch of dentistry, has accumulated a larger literature than any other aspect of dental science. In spite of this we are still distressingly ignorant of the ætiology of irregularities of the teeth, our treatment is correspondingly empirical, and a book which purports to unravel the complex factors concerned in the variations in the forms of the jaws deserves serious consideration. Dr. Sim Wallace has published in the form of a monograph [1] his successful thesis in competition for the Cartwright Prize of the Royal College of Surgeons, and has provided a stimulating and valuable contribution to the ætiology of deformities of the jaws and the concomitant irregularities of the dental arches. He recognises three main factors which may interfere with the normal development of the jaws and lead to irregularity of the teeth. They are: (1) developmental aberrations, such as accessory teeth, absence of teeth, cleft palate, &c.; these are relatively few in number and unimportant. (2) Local displacements, such as the irregularities produced by thumb-sucking, the prolonged retention of a temporary tooth or premature loss of the temporary teeth; these again are a well-recognised group of factors whose action is understood. (3) Subnormal development of the jaw-bones caused by harmful stimuli such as toxins or lack of the normal functional stimuli. This last group, the most important, is the one that presents so many difficulties both of explanation and treatment. The whole trend of orthodontic literature is to dismiss local factors as being of relatively small importance and to lay stress on the early and constitutional origin of defective bone-growth of the jaws. Dr. Wallace's analysis of the component factors in development is shrewd and logical, and his book does much to strengthen the view that general irregularities of the teeth arise in early life and spring from errors in growth, both of deficiency and excess. Though this is a big step forward it remains necessary to apply the hypothesis to the four main groups of malocclusion—namely, inferior protrusion, superior protrusion, inferior retrusion, and open bite. In what ways are these widely differing conditions produced? Here Dr. Wallace's book is less satisfactory, and leaves an impression that the real problem has only been pushed back a stage and in essentials is still unsolved. The author's account of the genesis of these irregularities is ingenious but often hypothetical. We do not find ourselves always in agreement with his observations and still less with all his deductions. Thus it is impossible to accept the statement "that few if any cases of crowding of the temporary teeth in early childhood have ever been recorded," for examination of a large number of children shows that definite crowding is far from uncommon though not so obvious as will be seen later in the same child when the permanent teeth are coming through. In the account of post-normal occlusion or inferior retrusion no mention is made of that variety in which the upper incisors are also retruded instead of being protruded. It is obvious that while both types have in common the post-normal occlusion of the lower teeth, yet there must be dissimilar factors at work to produce the great difference in the upper dental arch in these two types. We are glad to note that Dr. Wallace emphasises the early age at which inferior retrusion becomes established "even before the eruption of the temporary teeth"; there is an increasing body of evidence to suggest that this irregularity may be present at birth and represent a condition developed in utero. Certain redundancies and repetitions might perhaps have been avoided, but the book is admirably produced and illustrated, and merits careful study, not only by dentists, but also by anatomists and anthropologists.

[1] Variations in the Form of the Jaws. By J. Sim Wallace, M.D., D.Sc., L.D.S., Lecturer on Preventive Dentistry, King's College Hospital. London: Baillière, Tindall and Cox. 1927. Pp. 265. 17*s.* 6*d.*

HOSPITAL SERVICE IN AMERICA.

THE hospital service, general and special, of the United States is much more extensive, in proportion to population, than in our own islands. Comparisons of efficiency would be difficult and unprofitable, but we know that the best American hospitals are, in essentials, as good as our own best, while in mechanical detail a few of them are even more advanced, chiefly because they are newer and have been able to adopt the latest ideals of construction and equipment. The existence of so many curative institutions of varying character and importance has long made it desirable that some kind of "Statistical Abstract" of them should be made available. This laborious task has just been completed, for the time being, by the American Medical Association, which, through the Hospital Number of its *Journal*, has issued a complete list of all the hospitals which it recognises. This list forms its first Hospital Register, and is so fully documented as to provide a model of what such a register should be. The outcome of the Association's inquiries is the admission to the Register of 6807

hospitals and sanatoriums, and the exclusion of 462, containing over 11,000 beds. Good reasons are given for the exclusions; some of the institutions are deemed to be controlled by "persons known to be impostors and incapable, either morally or professionally, of providing efficient care for the sick or injured," some are suspected of exploiting quack cures for cancer, consumption and the like, others of permitting criminal or otherwise unethical practices to be carried on. The existence of institutions of doubtful reputation is the most conclusive justification, were any justification needed, for the preparation of a Register of Hospitals recognised by the medical profession in America. Their elimination is a duty which falls to the individual States afflicted by their presence. The geographical distribution of the American hospitals is necessarily very unequal, varying with the population. Thus while there are only ten general hospitals in Delaware, with a population only about double that of Hammersmith, there are 323 in the State of New York, with a population midway between 11 and 12 millions. Roughly two-thirds of the hospitals registered are general hospitals, and their 345,000 beds contain an average of 228,000 patients. Next to them come the 503 institutions for nervous and mental cases, with 373,000 beds, a comparatively narrow margin of which are unoccupied. The figures of maternity hospitals are curiously unexpected. There are only 178 of them limited to maternity cases, with only 5747 beds, and an average of 3695 patients, a fall in number of 84 in the last five years. Thus only about one-tenth of the maternity work is done in the special hospitals. On the other hand, in the same period the number of hospitals used mainly for industrial patients has much more than doubled, though apparently in the most highly industrialised States what may be called the industrial hospitals are comparatively few. It is less surprising, in view of the developments of recent years, to find that the orthopædic hospitals have nearly doubled in number in the last half decade. The American Medical Association finds that there is an increasing tendency for "the Government to assume functions heretofore belonging to volunteer agencies," but it should be explained that the word 'Government" is used to cover not only Federal, but State and municipal institutions. In America religious bodies have always had a strong inclination to maintain hospitals of their own, and there are over 1000 of these confessional institutions with 108,000 beds. It is, however, impossible to confine their benefits to members of the religious bodies concerned, the more especially since a fair amount of support is received from undenominational sources. It is instructive to find that of the 6807 hospitals on the Register 2091 now have physical therapy departments. In a country like America, divided into some 50 or so virtually independent States, Federal action in regard to hospitals would be exceedingly difficult, if not impossible, and there is consequently all the more reason to be grateful for the admirable work done by the Medical Association, and for its bold and decided action in refusing admission to its Register to any institution which fails to conform to elementary professional or moral standards. That action must lead eventually to the elimination of the unworthy.

THE TUBER CINEREUM AND ITS FUNCTIONS.

Two French workers, J. Camus and G. Roussy have done much to confirm the contentions originally made by Jakob Erdheim that centres lying in the floor of the third ventricle have functions with which the pituitary was till recently credited. These authorities showed that the polyuria which followed operative removal of the pituitary was due to damage of the neighbourhood of the tuber cinereum. This polyuria can be produced experimentally by a lesion which leaves the pituitary intact but injures the ventral nucleus of the tuber which is superficially situated. It is usually transitory but may be permanent, in such cases amounting to a true diabetes insipidus. The physiology of diabetes insipidus is still obscure. It has been shown to occur in animals with denervated kidneys and seems therefore to depend upon changes in the blood, though none has been demonstrated by biochemical methods. Camus, J. J. Gournay, and E. Fiterre found that in experimental diabetes insipidus in dogs, produced by piqure of the tuber cinereum, the uric acid tended to disappear from the urine while there was concurrently a great rise in the urinary excretion of purine bases. They believe therefore that the disorder is primarily metabolic, and that the polyuria is a secondary symptom. Both obesity and genital atrophy have been produced in animals by Camus and Roussy by means of experimental lesions of the centres of the tuber. Either may occur alone, or both may be present together, as in the dystrophia adiposo-genitalis of Fröhlich. Lesions of the paraventricular nucleus of the tuber have been shown to produce glycosuria, which, however, is only transitory. Disturbances of temperature regulation and of sleep rhythm have also been described. These researches initiated and continued by French workers seem to have left the pituitary with no function but that of regulating the growth of bones. They raise many problems for which no solution is at present forthcoming, in particular how we are to explain the pharmacological effects of pituitary extract upon diabetes insipidus and insulin hypoglycæmia if the pituitary body itself is not concerned in the metabolism either of water or of carbohydrate. Prof. Léon Binet, commenting on this difficulty in a summary[1] of recent advances in physiology, complains of the tendency of some investigators to accept the reality of pathogenic mechanisms while relying for support upon the results of injections of glandular extracts. It is tempting enough to accept such results as a simple phenomenon of cause and effect, but the curious contradictions that arise prove that more complex processes are often involved. Prof. Binet reviews a number of physiological topics, ranging from the function of the appendix to the physiology of thirst, and from tobacco-smoking to the effects of ablation of the cerebral cortex, with equal shrewdness. Each chapter is well supplied with references mainly to French authorities. The whole provides in a small compass a survey of the main lines along which physiological investigation is proceeding in France; the researches on the centres of the tuber cinereum are certainly among the most important of these and deserve attention.

HUMIDITY AND WEAVING.

A CONTROVERSY which has troubled the cotton trade for over 50 years bids fair at last to come to settlement. It concerns the influence upon health of introducing artificial humidity into weaving sheds in order to assist the manufacture of cotton cloth; this humidification is usually effected by blowing in steam, but in some cases by atomised water. The operatives have long maintained that the humidity exerts an injurious effect upon them; and many Governmental inquiries, as well as three Cotton Cloth Factories Acts, have aimed at minimising the injury. We now have before us a further report,[2] based upon two recent investigations. Of these the one by F. T. Peirce is entirely technical and deals with the effect of humidity on cotton yarns; the other is an intensive and exact inquiry by A. B. Hill, which shows, contrary to past allegation, no evidence that employment in humidified sheds gives rise to more sickness than in so-called "dry" sheds. Whatever may have been the case in the past when longer hours were worked and less was done to keep down the temperature, to-day the one class of shed appears to be no more injurious to the health of the weavers than

[1] Questions physiologiques d'actualité. By Léon Binet, Professeur agrégé de Physiologie à la Faculté de Médecine de Paris. Paris: Masson et Cie. 1927. Pp. 227. Fr.18.

[2] Report of the Departmental Committee on Artificial Humidity in Cotton Cloth Factories, H.M.S.O. 1928. 1s. 3d.

is the other. This statement is true where the sheds are grouped by thermometer readings or where humidity is artificially introduced. The fact, however, became clear that the atmosphere in many so-called "dry" sheds contained as much moisture as in humidified sheds. Hence, the recommendation is made to abolish any legal distinction between the two types of weaving shed when establishing regulations for maintaining atmospheric conditions favourable both for the efficiency of the weaver and for the quality of the cloth. Such optimal conditions appear to prevail at dry-bulb temperatures between 72·5° and 75° F., with a relative humidity of 75–80 per cent. It is therefore proposed that artificial humidification shall cease at 72·5° F. wet-bulb instead of at 75° F. as heretofore. Advantage is to be gained at such temperatures from local air movement, obtained by paddle fans, which cools the weaver but does not appreciably affect the warp thread; means to this end have not yet been perfected. Having regard to physiological evidence as to the influence of high wet-bulb temperatures upon health, the proposal is made that when the wet-bulb reaches 80° F. all work shall cease in any given shed, and the workers shall leave the premises. This course may seem stringent, but in practice the number of sheds affected should not be high, and it is just these sheds which should take more effective steps to improve their working conditions. This report is an excellent example of the application of modern knowledge to industrial practice.

THE Linacre lecture, of St. John's College, will be delivered by Sir George Newman at 3 P.M., on Saturday, May 5th, at the Arts School, Cambridge. His subject will be Linacre's Influence on English Medicine.

THE death is reported from Taunton of Dr. James Alexander Macdonald, at the age of 78. Dr. Macdonald was a Direct Representative on the General Medical Council, and served as chairman of the Council of the British Medical Association from 1911 to 1920.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. C. H. Dawe is placed on the Retd. List with the rank of Surg. Capt.

W. W. Darley and F. C. M. Bamford to be Surg. Lts.

Surg. Comdrs.: R. J. Inman to *Marlborough*; A. J. Tozer to *Victory*, for R.N. Barracks, Portsmouth; A. G. Bee to *Champion*; G. Carlisle to *President*, for three months' post-graduate course; and F. E. Scargill to *Nelson*, temp.

ROYAL ARMY MEDICAL CORPS.

Temp. Lt. F. R. How relinquishes his commn.

TERRITORIAL ARMY.

Capts. D. Stewart and J. P. Clarke to be Majs.

Lts. D. L. Kerr, J. C. Adam, W. A. Ramsay, and W. B. A. Lewis to be Capts.

H. W. L. Nichols, late R.F.A. Spec. Res., to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. G. F. Shepherd, from the Active List, to be Capt.

ARMY DENTAL CORPS.

Capts. to be Majs.: F. H. W. Beer, J. P. Duguid, and T. K. Place.

Temp. Capt. T. G. Doig, Dental Surg., Gen. List, to be Capt.

ROYAL AIR FORCE.

Flying Officers R. J. I. Bell and R. G. Freeman are promoted to the rank of Flight Lts.

INDIAN MEDICAL SERVICE.

Lt.-Col. R. W. Anthony to be Maj-Gen.

Capt. W. E. R. Dimond to be Maj.

Temp. Capt. Chandrian Krishna Row, the relinquishment of whose temp. commn. has been announced, is granted the rank of Capt.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXIII.

THE TREATMENT OF THE COMMONER INJURIES OF THE CARPUS.

THE mechanism of the wrist is unique among the articulations of the human body. It allows more kinds of movement than any other joint, and it takes a great part in the finely coördinated actions which characterise the hand. In the normal wrist a good many landmarks can be made out by palpation. In a case of recent injury, however, inflammatory swelling generally masks all or most of these points, and it is from radiographs that definite information must be sought.

It is therefore of importance to consider the manner of the use of X rays. In all cases two views should be taken with the forearm in full supination, one antero-posterior and one lateral. The lateral view should be taken with the radius and outer side of the wrist resting on the plate and the hand and fingers in line with the forearm. In cases of doubt it may be advisable to take a third, an oblique view, from a point midway between the two others. In cases of unilateral injury radiograms of the sound wrist should always be taken for the purposes of comparison. The first point to be ascertained in examining radiographs is the integrity of the individual carpal bones.

If there is no obvious fracture, the contours of the carpal condyle should be closely studied. Any interruption or irregularity of its line of curvature, either in an antero-posterior or lateral view, is evidence of displacement or fracture of the scaphoid or semilunar, which if not corrected leads to arthritis, or at least to loss of smooth working of the joint. Gross displacement of a bone or bones will be obvious, but slight chipping of the edge of the articular surface of the radius may be less easy to detect, although such an injury may lead to ankylosis of the wrist. Fracture of either styloid process is generally obvious enough. The scaphoid, although not fractured, may be so tilted round a transverse axis as to cast an almost circular shadow on the plate in an antero-posterior view, but viewed in profile its kidney shape will be evident with its lower end projecting forwards beyond the neighbouring carpal bones.

In all carpal injuries symptoms attributable to interference with the median or ulnar nerves are likely to be encountered, especially in cases of dislocation. These include loss of sensation, pain, and in long-standing dislocations trophic signs, such as glossy skin.

According to Destot of Lyons, fractures of the scaphoid or semilunar and dislocation of the latter account for 95 per cent. of injuries to the wrist, excluding sprains.

Sprains.

The symptoms of sprain of the wrist are familiar and in no essential way different from those of carpal fracture. Differential diagnosis depends upon a careful study of X ray plates. When this provides no evidence of fracture or dislocation, sprain may be assumed by a process of elimination. Pain, stiffness, and swelling are the outstanding symptoms. Small marginal fractures of the radius are to be carefully looked for, and if found the case must be treated as of more gravity than a simple sprain, although the lines of treatment will be the same. Rest on a light palmar splint extending from the upper third of the forearm to the heads of the metacarpal bones, and supported by a sling, is advisable. Gentle movements of the fingers and thumb should be encouraged from the first. Massage is not recommended. The length of time during which the splint should be worn must depend upon the duration of the pain and swelling; in most cases of average severity a fortnight should suffice.

Simple Fracture of the Scaphoid.

Simple fractures of the scaphoid are almost invariably caused by falls on the extended hand and fingers, or by violence applied in the same direction, as in a man who tried to fend off a motor-car by pushing forcibly against its radiator with his hand. Falls from a height may cause extrusion of a carpal bone through the skin of the palm, as in a specimen in the Museum of St. George's Hospital, referred to by Mr. Hulke, in Holmes's "System of Surgery" (third edition, 1870, ii., 834), in which both semilunars were so extruded, one of them merely hanging by a small shred of ligament. In this case the forearm bones also projected through the skin. Such violence may cause fracture of the radius, with or without gross carpal injury, or the scaphoid may score the articular surface of the radius and itself escape fracture, or both the radius and the scaphoid may be broken at the same time. Many experiments have been made on the dead body with various results, but it is impossible in the cadaver to reproduce the conditions present in life, particularly as no artificial substitute can be found for muscular action, which by fixing the joint in a given position, must influence the nature of the resulting injury. All that is certain is that if the brunt of the blow is taken by the outer side of the palm the scaphoid is most likely to suffer, and if the hypothenar eminence is most exposed to violence the semilunar is likely to be dislocated or broken.

Cases of simple fracture of the scaphoid, without displacement, should be treated as sprains, the fragments having presumably sprung back into position after the momentary displacement which accompanied the original violence. If the wrist is locked, or if the displaced bone can be felt filling up the hollow of the snuff-box, or the X rays show undue separation of the scaphoid and semilunar bones an anæsthetic should be given and the hand and wrist forcibly flexed and adducted, while with two thumbs the surgeon presses through the anatomical snuff-box upon the fragments, so as to readjust them to the head of the os magnum. The after-treatment is the same as for sprain. The injury may be immediately disabling, but it is on record that gymnasts and boxers and other athletes have incurred fracture as demonstrated by X rays without ceasing their activities, although for a month or two some weakness may be felt. The condition of the upper surface of the carpal condyle, as seen in antero-posterior and lateral X ray plates, will influence the surgeon in his treatment. In all carpal displacements radiographs should be taken after, as well as before, attempts at reduction in order to make sure of true correction. If reduction is unattainable, or if pain and disability persist after some weeks, it is advisable to excise the separated head of the bone through an incision running from the styloid process of the radius to the base of the first metacarpal bone, thus exposing the snuff-box.

Fracture and Dislocation of the Semilunar Bone.

The elongated curved form of the scaphoid renders it more easily broken than the semilunar, whose form is more compact and its mobility greater. Dislocations of the semilunar bone are generally the result of falls or blows, but may be produced by violent torsion of the hand.

Unlike most carpal injuries, fractures of the semilunar are generally produced with the wrist and fingers flexed, as in grasping a hammer, crow-bar, or the starting lever of a motor-car.

Out of 24 cases of fractured semilunar recorded by Destot ten were unaccompanied by other lesions of importance. The remaining 14 were complicated by other injuries of the wrist. These were practically unknown until the introduction of X rays, on which the diagnosis depends. The outline of the carpal condyle will be broken if any displacement has occurred. A fractured semilunar alone is of no more importance than a sprain and should be treated as such.

The semilunar is rarely dislocated and fractured at the same time. In an extensive dislocation the ligaments are necessarily much torn and replacement may be difficult. If the semilunar is nearly, or completely, freed from its ligamentous attachments, its reduction is of doubtful value, as its nutrition must be seriously impaired.

The symptoms are typical, but the patient may not complain much unless the nerves are affected. The wrist is swollen and globular, with an increase more in the antero-posterior than in the transverse measurement, and this swelling is situated below the interstyloid line, which keeps its normal obliquity. There is no silver-fork deformity. The fingers are semi-flexed. The wrist is locked, and in case of gross displacement the ulna nerve is likely to be pressed upon and pain or anæsthesia in the region of its supply may be detected. The median nerve may also suffer. Some active movements of the fingers may be possible and some passive extension of the wrist, but not flexion. Lateral movements are also blocked. Pronation and supination are restrained by pain. The dislocated bone may in some cases be felt under the skin. Such an injury is rarely complicated by typical fracture of the radius for the force is generally spent in the wrist and in partial fractures of the extremity of the forearm.

Nervous troubles may occur without dislocation, as in cases of fracture of the radius or of the scaphoid, which last may affect the median nerve.

Apart from X ray evidence, the projection in the carpal hollow of the semilunar, along with its mobility on flexion, is the best clinical sign of its dislocation.

Reduction should be attempted in all cases, except where the semilunar is obviously freed from its attachments so as to form a loose body beneath the skin, in which case it should be excised. Destot gives the following instructions for reduction:—

An anæsthetic is necessary. The supinated forearm should be firmly fixed by an assistant on a strong table with the hand just over its edge. The surgeon mobilises the wrist by means of movements in all directions. He then grasping the patient's hand with both his own, pulls forcibly in the axis of the forearm, keeping the wrist in hyperextension and adducting it with a view to opening the articulation. When the axis traction is thought to be enough, one hand relinquishes its grasp and seeks the projection made by the semilunar on the front of the wrist. With the finger this is pressed backwards into the joint under the end of the radius while the hand is brought from hyperextension into flexion. The object of the hyperextension is exposure of the head of the os magnum over which the semilunar must be pushed into position. The scaphoid can be left to find its place itself, but if it is broken, pressure in the snuff-box with the hand in forced adduction should replace the fragment.

The sooner such a reduction is made the better but it may be successful up to three weeks after the injury. In old-standing cases, when there is much disability or pain, excision is advisable. Haughton and Holt reported excision of the whole of the first row of carpal bones with a good result.

The forearm and wrist and hand should be put up in plaster in the position of flexion and slight adduction after reduction. At the end of three days the plaster distal to the metacarpus may be removed, so as to allow of passive and afterwards active finger movements. At the end of three weeks the whole splint may be removed and a sling substituted.

Rare injuries do not come within the scope of this article, but it should be noted that dislocation forwards of the cuneiform causes acute nerve symptoms and immediate reduction or excision is imperative.

E. MUIRHEAD LITTLE, F.R.C.S.Eng.,
Consulting Surgeon, Royal National Orthopædic Hospital.

MATERNAL MORTALITY IN HOSPITAL.—The hon. secretary of the British Hospital for Mothers and Babies at Woolwich states that no maternal death has occurred in the last 1300 cases. Since the new building was opened in March, 1922, there have been more than 3000 in-patients and not one death from sepsis.

AN INQUIRY INTO THE RESULTS OF THE LIVER TREATMENT OF PERNICIOUS ANÆMIA.

IN a preliminary report by the Medical Research Council published a few weeks ago (THE LANCET, March 10th, p. 514) it was stated that the treatment of pernicious anæmia by addition of liver to the diet, introduced in America by Minot and Murphy, has already been widely adopted with encouraging results. In order to ascertain the nature of these results we asked a representative group of clinicians to send us a schedule of cases showing the proportion of successes and failures, and to supply information on the following points:—

1. The dose of whole liver employed.
2. The efficiency of the liver extracts tested.
3. The nature of any other treatment given simultaneously.
4. Whether the cases which failed to respond were proven cases of pernicious anæmia as judged by (*a*) history of previous relapse, (*b*) typical blood picture, (*c*) achlorhydria.
5. If any cases of subacute combined degeneration (S.C.D.) were tested and with what result.
6. Any experience of liver treatment in cases of (*a*) secondary anæmia, (*b*) aplastic anæmia.
7. If any evidence was obtained of the disappearance of achlorhydria under treatment.

The replies, along with a number of interesting comments, are here set out.

TWENTY-ONE CASES[1] TREATED AT ST. BARTHOLOMEW'S HOSPITAL, LONDON.

Reported by Prof. F. R. FRASER, M.D., F.R.C.P.,
DIRECTOR OF THE MEDICAL PROFESSORIAL CLINIC.

	Cases treated with—	
	Liver diet.	Liver extract.
Apparently cured	15	3
Improved but relapsed	1	—
Failed to respond at all ..	2	—
Total	18	3

Notes to Schedule.

One case put on liver during remission produced by arsenic kept well for four months, but subsequently died of an intercurrent appendicitis with general peritonitis.

One case responded with a rise in reticulated red cells following whole liver administration, but owing to onset of severe heart failure treatment was abandoned. This patient is now dead.

The three cases treated with liver extract were afterwards given liver diet following the production of reticulocyte crisis by the extract used.

One of the cases which failed to respond had liver extract as well as whole liver.

Replies to Questions.

Dose of Whole Liver.—Half a pound daily, either lightly cooked or raw in form of pulp, reduced when red blood cells reach a normal figure.

Extracts Tested.—(*a*) Eli Lilly and Co.; (*b*) Medical Research Council. Both were efficient in a dose equivalent to 500 g. whole liver daily.

Simultaneous Treatment.—Of the (ten) cases which came under observation in the stage of relapse or before the first remission, all had hydrochloric acid after the immediate effects of liver were observed. The remainder comprise cases in which liver was added to pre-existing therapy—hydrochloric acid, or arsenic, or both—the patients being in a remission. The value of these is that they have remained well since the addition of liver, the longest interval now of this series being 12 months. Five have red cell counts of over 5,000,000, two of over 4,000,000, and one of 3,500,000.

Failure to Respond.—In neither of the two cases which failed to respond was there a history of a previous relapse. In both the blood picture was compatible with a diagnosis of pernicious anæmia, and both showed achlorhydria with a low total chloride content in a fractional test-meal. A point of similarity in these two cases is the fact that in each the anæmia followed an acute respiratory infection; neither showed any signs of subacute combined degeneration. The autopsy findings on one were, except for the absence of any degenerative changes in the nervous system, compatible with a diagnosis of pernicious anæmia. The other case is still under observation.

Cases of S.C.D.—Of the (ten) cases which came under observation in the stage of relapse, or before the first remission, the eight who responded showed objective evidence of involvement of the nervous system. So far there have been no diminution in these signs. The two cases in this series whose anæmia did not respond to liver had, as above stated, no signs of subacute combined degeneration.

Secondary and Aplastic Anæmias.—Five cases of secondary anæmia were given whole liver feeding. In none was there a characteristic response in reticulated red cells, and it was difficult to ascribe any slight improvement to liver therapy. One case of aplastic anæmia was treated with whole liver with no benefit.

Achlorhydria.—In only one case were the stomach contents examined both before and after treatment. The achlorhydria has persisted. It has been noted that several patients feel benefited by the continuance of the administration of hydrochloric acid, although their blood count has resumed a normal picture.

[1] These cases were reported in greater detail in the Brit. Med. Jour., Feb. 4th, 1928, p. 165.

TWENTY CASES TREATED AT THE LONDON HOSPITAL.

Reported by P. N. PANTON, M.B.,
DIRECTOR OF THE HALE CLINICAL LABORATORIES;
AND
F. C. O. VALENTINE, M.R.C.P.,
ASSISTANT DIRECTOR.

A TRUE estimation of the value of the Minot-Murphy diet can scarcely be arrived at in a period of less than ten years, and any conclusions reached from a consideration of the cases presented by us must carry less weight than those described in the American literature owing to the small number of our patients and the short periods during which they were observed.

Methods of Comparison.

Two methods are open to us. By the first we may compare the effect of the treatment during arbitrary periods over a series of patients and for this purpose we have divided the cases into groups corresponding to the length of observation. If it can be shown that there is a fairly constant response to the liver treatment, as indicated by the temporary rise in the reticulocyte count, the steady increase in red cell and hæmoglobin content, improvement in the general health and freedom from relapse, we help to corroborate the prima facie case which has already been made out for the value of the treatment. By the second method we may compare the condition of these patients during these periods with that of another series of patients treated by other methods. Such comparison may be most fallacious if we depend upon our recollection of the effect of treatment in pernicious anæmia before the discovery of the liver diet, but we are fortunate in having at our disposal the complete data of a large series of cases.[1] Such comparison appears to us to be justifiable and to lead to conclusions which admit of little doubt.

The Present Series.

The present series of cases includes 20 examples of pernicious anæmia, and of these eight showed evidence of spinal cord involvement, one case of sprue with a typical primary anæmia blood picture, one case of subacute combined degeneration of the cord without blood changes, and one case of hæmolytic icterus. The old series comprised 114 consecutive cases of pernicious anæmia seen between the years 1909 and 1919 inclusive.

The only patient of this series known to be still surviving is a man first seen in 1909 with a typical blood picture, achylia, and definite cord changes. Now, nearly 20 years later, he is in active employment and good physical condition with a normal blood state, the spinal condition being unaltered. During this period the patient has taken an ordinary diet of average protein content and states that he dislikes liver and has rarely eaten it.

The 20 examples of pernicious anæmia treated with liver, either in the fresh state or as the extract, are divided into four groups. Group 1, of seven cases observed for three months or less; Group 2, of eight cases observed from three to six months; Group 3, of three cases observed from six to nine months; and Group 4, of two cases observed for over nine months. The red cell count is a fair guide to progress under treatment, and the table gives a brief summary of the cases in their four groups.

Replies to Questions.

Dosage.—Of the 20 cases, four were treated with liver extract. In these patients daily reticulocyte counts were made, and in each case the usual rise and subsequent fall in the percentage of these cells were observed. In two of these cases HCl was added to the treatment about a fortnight later, after the activity of the extract had been demonstrated by the reticulocyte curve and a definite increase in the red cell count. Of the remaining 16 cases, five were put on liver alone and 11 on arsenic or HCl, or both in addition. One case was originally treated (in July, 1926) with a high protein diet, including liver, and was subsequently placed on liver diet. The average amount of liver given was ½ lb. a day, and of liver extract the equivalent of 1 lb. of fresh liver daily, while in hospital. The liver was given both lightly cooked and in the raw state as "cocktails." Both forms appeared to be effective, the cocktails being perhaps the more palatable. The amount taken by the patients in their own homes varied considerably in individual cases. It is known that Cases 1 and 6 failed to take their liver regularly.

Cases of S.C.D.—Eight of these cases of pernicious anæmia showed in varying degree the symptoms and signs of subacute combined degeneration of the cord. We consider that these cases have been under observation for far too short a time to warrant a statement that the cord changes do or do not progress under liver treatment. One additional case, however, of subacute combined degeneration in which there was no anæmia is of interest as he has been on liver for 15 months. Careful examination made at the beginning and end of this period by the same observer showed that no change had occurred in the physical signs, though the patient himself considered that he was slightly weaker. It should also be mentioned that in the one surviving case quoted above, from the earlier series, the cord lesions from the time of disappearance of anæmia—i.e., during 19 years—have remained unaltered.

Achlorhydria.—All these cases had achylia, eight being examined by means of a fractional test-meal, the rest by the ordinary Ewald meal. No re-examination of the gastric juice has been made up to the present.

Two other cases should also be described.

The first had had sprue for 20 years and when first seen his red count was 400,000. After a blood transfusion of 200 c.cm. he was put on liver soup, and the count rose to 1,800,000 in one week. After nine months the red cell count was 6,150,000. Incidentally, three weeks after starting on liver, he had an attack resembling acute gout affecting the toe-joint.

The second case was that of a woman suffering from hæmolytic icterus. She was only kept on liver diet for about ten days, and no rise in the red cell count could be traced. The percentage of reticulocytes rose from about 45 per cent. to 65 per cent. while she was taking liver, but this was not necessarily due to the diet, since considerable variation occurred when this factor was absent.

Comments.

Anyone acquainted with the results of treatment in pernicious anæmia before the discovery of liver diet would regard the results recorded in this small series of cases as encouraging, but would recall some patients in whom unexpected and rapid remissions occurred, and others in whom the disease dragged out a long course of many years. In making a comparison with the course of the disorder observed in the older and longer series, we believed that deductions might be drawn if we considered all the cases at the same intervals of time and noted how many patients improved, relapsed, or died in these intervals.

It was found that at the end of three months after their first admission to hospital, out of 114 cases in the earlier series, 37, or 31·2 per cent., were dead; after six months, 50, or 43·9 per cent., were dead; and four others, or 3·5 per cent., had

[1] Panton, P. N., Maitland-Jones, A. G., and Riddoch, G.: Pernicious Anæmia: An Analysis of 117 Cases, THE LANCET, 1923, i., 274.

relapsed; after nine months 60, or 52·6 per cent., were dead, and eight, or 7 per cent., had relapsed.

A conceivable explanation of the overwhelming difference between the results in the two series may lie in the possibility that, owing to the general interest aroused by the new treatment, patients present themselves for examination at an earlier stage. Such explanation may be true in part, and is perhaps reasonably examined by comparing the average red cell count on admission to hospital in the two series. This average in the first series was 1,387,000, and in the second 1,790,000. The difference is in favour of the second series, but is hardly greater than, owing to the smaller numbers, might occur by chance, and is certainly not sufficient to account for the discrepancy in the courses run.

We do not yet know if patients with pernicious anæmia will respond indefinitely to liver taken by the mouth, or if they will ever be able to leave off the treatment, but the remarkable experience in following up the first series of cases of interviewing a succession of sick persons or sad relatives, and in the second series of seeing nothing but hopeful patients, convinces us that the Minot-Murphy discovery ranks as a therapeutic advance of the first importance.

Our thanks are due to the physicians of the London Hospital for allowing us to publish these results.

SIX CASES TREATED AT ST. MARY'S HOSPITAL, LONDON.

Reported by Prof. F. S. LANGMEAD, M.D., F.R.C.P., *and* C. M. WILSON, M.D., F.R.C.P.,
PHYSICIANS TO THE HOSPITAL.

	Cases treated with liver diet.
Apparently cured	6
Improved but relapsed	0
Failed to respond at all	0
Total	6

Replies to Questions.

Dose of Whole Liver.—Half a pound of cooked liver daily, preceded in one case by ¼ lb. cooked liver daily.

Simultaneous Treatment.—None in two, hydrochloric acid in four. Arsenic in one, during a period when only ¼ lb. of liver was given daily, but improvement was enhanced when the dose of liver was increased to ½ lb. daily and the arsenic was stopped.

Cases of S.C.D.—No cases of subacute combined degeneration were treated, but symptoms referable to the nervous system were present in four; these d sappeared under treatment in three, whilst in the fourth the subjective symptoms went but the knee- and ankle-jerks remained absent.

Achlorhydria.—The gastric contents were examined in three before and after treatment, achlorhydria was present in one and achylic gastrica in two; in no instance were these abnormalities corrected by the treatment.

Comments.

In one case the patient, after ten weeks of liver treatment, walked without effort and returned to active life after having been in bed for two years. In three considerable improvement had already followed other treatment. In one of these ultra-violet light had been used with arsenic, in another treatment by a blood extract (specially prepared by Dr. A. C. Alport) and later by arsenic, and in the third by an initial transfusion followed by ultra-violet light. When these treatments were superseded by liver alone, slow, but definite, improvement was replaced by rapid improvement leading to apparent cure.

Two Cases Related.

CASE 1.—Male aged 41. Duration of illness five months before admission. Increasing pallor, weakness, palpitation. Exhausted after five minutes' walk to business. Achlorhydria. No nervous symptoms. Blood count: Red blood cells, 1,320,000; Hb., 32 per cent.; colour-index, 1·25; white blood cells, 5500. Differential count: Polymorphs, 66 per cent.; small lymphocytes, 32 per cent.; large lymphocytes, 1 per cent.; eosinophils, 1 per cent.; characteristic changes in red blood cells.

Treatment.—1. Ultra-violet light, arsenic, hydrochloric acid. Two weeks later little or no improvement. Red blood cells, 1,500,000 per c.mm.; Hb., 32 per cent.; C.I., 1·1; white blood cells, 6100. Differential count: Polymorphs, 69 per cent.; small lymphocytes, 20 per cent.; large lymphocytes, 8 per cent.; hyalines, 1 per cent.; mast cells, 2 per cent.

2. Several teeth removed after X ray examination had revealed considerable apical sepsis, and afterwards the same treatment followed. Considerable improvement, and when discharged five weeks later, blood examination as follows: Red blood cells, 2,960,000; Hb., 76 per cent.; C.I., 1·25.

3. After discharge, continued on same treatment and took, also, ¼ lb. cooked liver daily. Continued to improve and returned to work. Blood count six months after discharge: Red blood cells, 3,280,000; Hb., 76 per cent.; C.I., 1·2; white blood cells, 4400. Appearances of red cells nearly normal.

4. Liver increased to ½ lb. daily, arsenic and ultra-violet light stopped, HCl continued. Continued improvement. Blood count ten weeks later: Red blood cells, 4,500,000; Hb., 92 per cent.; C.I., 1·02; white blood cells, 7500. Differential count: Polymorphs, 58 per cent.; small lymphocytes, 14 per cent.; large lymphocytes, 13 per cent.; hyalines, 14 per cent.; eosinophils, 1 per cent.; red blood cells show very few changes.

He is in full work, looks well, and says that he feels better than he has done for many years. Achlorhydria still present.

Result.—No improvement until removal of focal sepsis, but improvement with As., HCl, and ultra-violet light after this was done. It continued after ultra-violet light replaced by ¼ lb. liver daily; enhanced when As. also stopped and liver increased to ½ lb. daily. HCl given throughout. Apparent cure except for persistent achlorhydria.

CASE 2.—Woman aged 53. Many partial remissions since onset of illness in 1912. In February, 1916, the red blood cells numbered 1,724,000, the hæmoglobin 35 per cent., whites 4800, and the differential count was as follows: Polymorphs, 50 per cent.; small mononuclears, 42·8 per cent.; large mononuclears, 4·4 per cent. In 1923 the red cells had fallen to 1,500,000 and the hæmoglobin to 30 per cent. At that time she complained of numbness of the feet and arms and the ankle-jerks and knee-jerks were absent. In September, 1927, the red cells numbered 1,900,000, and the hæmoglobin 40 per cent., normoblasts were present and the red cells were irregular in size and shape; she was admitted to hospital, where blood transfusion was carried out twice at intervals of a fortnight. There was a slight improvement in the blood picture. Fourteen days later she was put on ½ lb. cooked liver daily, which she has taken regularly since—that is, from Nov. 1st, 1927, until the present time. On March 25th, 1928, the red blood cells numbered 5,608,000; hæmoglobin, 85 per cent.; colour-index, 0·78; white blood cells, 11,000. The red cells were normal in size and shape, and no abnormal cells were seen in the film. In the differential white count the polymorphs numbered 44·3 per cent.; small mononuclears, 49 per cent; and the large mononuclears, 3·3 per cent. The nervous symptoms, such as numbness, were no longer present, but the knee-jerks and ankle-jerks were absent. Dr. W. G. Johnston, of Brixton, with whom I had seen the patient originally in consultation, tells me that during the time she was taking the liver there was no other treatment of any kind and that her diet was not altered except for the addition of liver.

FOUR CASES TREATED AT ST. THOMAS'S HOSPITAL, LONDON.

Reported by Prof. H. MACLEAN, M.D., F.R.C.P.,
DIRECTOR OF THE CLINICAL MEDICAL UNIT.

	Cases treated with liver diet.
Apparently cured	4
Improved but relapsed	0
Failed to respond at all	0
Total	4

Replies to Questions.

Dose of Whole Liver.—Half a pound, cooked, daily.

Extracts Tested.—One early extract used in one case of pernicious anæmia and in one case of myeloid

leukæmia. No improvement in either case, but extract was obviously inactive.

Simultaneous Treatment.—Arsenic in two cases. Hydrochloric acid in one.

Failure to Respond.—All responded well.

Cases of S.C.D.—One patient showed paræsthesia and sensory changes, which disappeared during treatment.

Achlorhydria.—No evidence of disappearance.

TWENTY-FIVE CASES TREATED AT UNIVERSITY COLLEGE HOSPITAL, LONDON.

Reported by JANET VAUGHAN, B.M., B.CH.,
FROM THE DEPARTMENT OF CLINICAL PATHOLOGY.

Disease.	Liver treatment.	Cases.	Cured.	Failed.
Group I.				
Pernicious anæmia..	Whole liver, 250 g. daily	8	8	—
	Liver extract ..	4	4	—
	Liver extract and whole liver ..	1(*a*)	1	—

	Liver extract ..	3	2	1(*c*)
	Total	7	5	2
Group III.				
Anæmia unassociated with hæmorrhage—				
1. Lymphatic leukæmia.	Whole liver, 250 g. daily	1	—	1
2. Lymphatic leukæmia.	Liver extract ..	1	—	1
3. Syphilitic spastic paraplegia.	Whole liver, 250 g. daily	1	—	1
4. Carcinoma of the prostate with secondary deposits in bones.	Whole liver, 250 g. daily, followed by liver extract	1	—	1
5. Secondary anæmia, cause unknown.	Whole liver, 250 g. daily	1	1	—
	Total	5	1	4

Notes to Schedule.

(*a*) One case which failed to respond to liver extract reacted later to whole liver 8 oz.

(*b*) Post operation bilateral femoral thrombosis associated with persistent pyrexia was present as a complicating factor in this case.

(*c*) Sufficient extract for a seven days' test only was available. Patient is now having whole liver, but treatment has not been continued long enough to draw any further conclusions.

Replies to Questions.

Dose of whole cooked liver, 250 g. a day. Dose of extract, 500–750 g. a day.

Extracts Tested.—In such a small series of cases it is difficult to reach any definite conclusions as to the comparative efficiency of the extracts tested, especially when the reaction time to whole liver would appear in some cases to be longer than the usual ten days. One case definitely failed to respond to doses of one extract up to an equivalent of 1250 g. of fresh liver a day for 18 days, and when given a different extract reacted dramatically on the fifth day. It is unlikely that there was any summation effect in this case, as a further patient on the second extract also responded on the fifth day.

Simultaneous Treatment.—Arsenic in three cases of pernicious anæmia.

Cases of S.C.D.—In one case no alteration in condition of the nervous system after two months' treatment, both with extract and whole liver, though improvement in blood picture. In a second case no alteration in condition of the nervous system after seven months' treatment with whole liver, though improvement in blood picture.

Achlorhydria.—No evidence was obtained as to its persistence.

Comments.

Three cases of pernicious anæmia showed a considerable delay in reaction: (1) Three months—during the first two months the patient was only taking very small quantities of whole liver, approximately 3 oz. daily, owing to persistent nausea. She then started to take the full diet with gradual improvement to a practically normal blood picture at the end of a further four months. (2) Twenty days—the first ten on extract, to which there was a definite recticular response and a slight rise in the red cells. The patient was then put on whole liver 8 oz., and at the end of a further ten days the red cells again rose, and continued rising, till normal figures were reached. (3) Forty-four days. Fifteen days non-commercial extract known to be active. No response. Twelve days non-commercial extract of unproved potency. Seventeen days whole liver 8 oz., followed by response.

A remarkable gain in weight was noted in all cases, especially those on whole liver. Details will be published later.

TWO CASES TREATED AT LEWISHAM HOSPITAL.

Reported by E. P. POULTON, M.D., F.R.C.P.,
CONSULTING PHYSICIAN TO THE HOSPITAL.

R. B., aged 57, married, had been operated on for gall-stones in January, 1927. She was admitted to Lewisham Hospital under the care of Dr. I. Lewis in a comatose condition, vomiting bile-stained fluid, and with ketonuria, on July 15th, 1927. For four weeks she had been suffering from pain and vomiting similar in character to her previous attack of gall-stones. The vomiting cleared up about ten days after admission. The spleen was palpable. The blood counts carried out by Dr. R. S. Ralph are shown in Table I. The report on the blood film of August 8th states:

TABLE I.

—	Date in 1927—					
	Aug. 2.	Oct. 7.	Oct. 19.	Nov. 10.	Nov. 21.	Dec. 5.
Hb. (per cent.)	25	20	37	55	65	78
Red cells (in thousands)	1,168	992	1,920	2,944	4,168	4,100

"The reds vary greatly in size. Macrocytes and microcytes are common, polychromasia is observed, and there are numerous poikilocytes. No nucleated forms could be seen." The serum gave a direct positive result to Van den Bergh's test. It was found impossible to carry out a test-meal examination. The patient was given ½ lb. of raw liver per day, beginning on Oct. 10th, and just previously to this the hæmoglobin had fallen to 20 per cent. Clinical improvement and improvement in the blood picture followed immediately. It is interesting to note that this was accompanied by an increase of the polymorphs and a diminution in the lymphocytes. She was discharged on Dec. 15th, 1927, and there is a note that "she now has the best colour of any patient in the ward." On Nov. 22nd she was ordered hydrochloric acid dil. ℥ i. in 4 oz. lemonade four times a day before meals.

The most striking point about this patient was the improvement in her nervous symptoms. On August 2nd a double extensor plantar response was found, and clumsiness in the use of the fingers showed that some subacute combined degeneration of the cord was present. On Dec. 1st the left plantar response was flexor, the right flexor first and subsequently extensor. She noticed that the clumsiness of her hands and fingers had improved. She was last seen

on March 6th. Since leaving the hospital she had been taking ¼ lb. of liver daily. The improvement in her hands and fingers was maintained; but she had an obviously spastic gait, and was compelled to walk with a stick.

B. J., aged 46, married, was admitted to Lewisham Hospital under the care of Dr. L. W. Hale on Jan. 10th, 1928. She came up complaining of "going off her legs." Dr. Ralph's blood counts are shown in Table II. The

TABLE II.

—	Date in 1928—		
	Jan. 13.	Feb. 13.	March 23.
Hb. (per cent.)	40	75	110
Red cells (in thousands) ..	2,272	3,724	5,900
C.I.	0·9	1·0	0·9
White cells	6,000	9,500	17,000
Polymorphs	2,460	3,280	6,630
Lymphocytes	3,240	3,800	5,600

Eosinophils	180	570	3,400
Mast cells	0	48	170
Myelocytes	0	95	—

report on the film of Jan. 13th stated: "The red cells vary greatly in size, and there is marked macrocytosis. Poikilocytes are common, as also are basophils, both of the punctate and diffuse variety. No nucleated forms were seen." A fractional test meal examined at intervals of half an hour, one hour, and one and a half hours, showed the absence of free hydrochloric acid and a maximal total acidity of 10 c.cm. N/10 acid per cent. She was at once given ¼ lb. of raw minced liver twice a day. This was taken in a cup of warm water to which half a cube of Oxo had been added. A remarkable improvement set in immediately, and at present (March 29th) she has an abnormally bright-red complexion. The red cells and hæmoglobin are now above the normal value. The white count (March 23rd) shows an increase of all the cells; the eosinophilia is the most marked feature; but the polymorphs are increased by 100 per cent. The red cells now vary only slightly in size. The last menstrual period before admission was in December, 1926. Now she has had a scanty period in February, 1928. On March 12th the resting juice and fractional test-meal examined at three-quarter hour intervals, again showed complete absence of free hydrochloric acid, and a maximal acidity of 20 c.cm. N/10 acid per cent. A similar result was again obtained at the beginning of April. So far no hydrochloric acid has been given to the patient.

During treatment this patient also showed marked improvement in her nervous symptoms. On admission the plantar responses were definitely extensor. She complained of numbness over her right arm, over both palms, and over the feet and the legs, extending up the lower third of the thighs. There was marked impairment to cotton-wool and pin-prick over these areas, and the patient could not sew or knit. Now (March 29th) the numbness has largely disappeared; but there is tingling of the palms. The sensation to pin-prick is almost perfect and the sensation to cotton-wool shows a marked improvement. She can knit and sew. The plantar response on the left is flexor at first and later extensor. The response on the right is extensor, but rather indefinite.

Owing to the great improvement in the symptoms due to subacute combined degeneration of the spinal cord in these cases, it has been considered best to give full details. My thanks are due to Dr. Lewis, Dr. Hale, and Dr. Ralph for supplying me with the necessary data, and to Dr. Humphrey Nockolds, superintendent of the hospital, for allowing the publication of the cases.

SEVEN CASES TREATED AT BIRMINGHAM.

Reported by A. P. THOMSON, M.D., M.R.C.P.,
ASSISTANT PHYSICIAN TO THE GENERAL HOSPITAL.

IN the cases (1 to 5 inclusive) in which the diagnosis of pernicious anæmia was reasonably certain the beneficial effect of the diet was remarkable. In Cases 1 and 5 no other treatment of any kind was employed (apart from rest in Case 5). The other three cases took arsenic in some form. No relapses have occurred, but only two cases have been treated for a year. In two cases (1 and 4) repeated fractional test-meals two months and eight months after beginning the diet showed no return of free hydrochloric acid. Case 6 was doubtful; it may have been true pernicious anæmia, but the history was not convincing, and I was, unfortunately, not given the opportunity of investigating a fractional test-meal. If this case was, in fact, one of secondary anæmia it is only one that has improved. I have notes of three other cases of secondary anæmia associated with chronic nephritis, tubercle, and hæmorrhoids, in which the liver diet appeared to have no effect. Two cases of subacute combined degeneration have been treated recently, but in neither of them was there any improvement in the nervous signs and the anæmia was only slightly reduced. Case 7 was interesting. The anæmia was aplastic in type and apparently due to benzol poisoning. No improvement followed liver diet or the use of liver extract. In all cases the liver was taken cooked, with the exception that Case 2 took a few sandwiches of raw liver in the early stages.

CASE 1.—Mr. A. B., aged 58. October, 1927: No sore tongue. Symptoms of anæmia "on and off" three years. Definite diagnosis two years ago—at time of relapse.

Blood: R.B.C., 1,100,000; W.B.C., 4600; Hb., 36 per cent. Films: Poikilocytosis and punctate basophilia very marked. Fract. test-meal: Absence of HCl.

Treatment: Liver diet. No other treatment; refused to rest.

December, 1927: R.B.C., 3,000,000; Hb., 75 per cent. Films normal. Fract. test-meal: Absence of HCl. March, 1928: Quite well; continuing diet.

CASE 2.—Mrs. C. D., aged 52. August 21st, 1927: Sore tongue many years. Marked anæmia six months, typical appearance. Spleen palpable, febrile for some weeks.

Blood: R.B.C., 1,100,000; W.B.C., 2700; Hb., 34 per cent.; index, 1·4. Films: Showed poikilocytosis and a few nucleated red cells.

Treatment: Liver diet (at first liver given raw, later cooked) and small doses of arsenic by mouth. Temperature became normal in two days. A course of N.A.B. given in September, 1927.

Progress: Uninterrupted. Sept. 25th: R.B.C., 3,400,000; Nov. 18th: R.B.C., 4,040,000. March 20th, 1928: R.B.C., 4,000,000; W.B.C., 7800; Hb., 95 per cent. Films normal. Spleen no longer palpable; feels perfectly well.

CASE 3.—Miss E. F., aged 39. Feb. 19th, 1927: Sore tongue three and a half years—very severe at times. Symptoms of anæmia six months. Spleen palpable.

Blood: R.B.C., 1,500,000; W.B.C., 6500; Hb., 48 per cent; index, 1·5. Films: Usual changes of P.A.

Treatment: Liver diet; course of N.A.B.; Ac. HCl dil.

Progress: Rapid; has been at work for six months.

Last blood examination Sept. 22nd, 1927: R.B.C., 5,500,000; Hb., 85 per cent. Films normal. Spleen not palpable.

CASE 4.—Mr. G. H., aged 52. Jan. 21st, 1927: Sore tongue four years ago. Rest cure for "nervous exhaustion" two years ago—(? relapse). Typical appearance; spleen palpable.

Blood: R.B.C., 1,200,000; W.B.C., 3200; Hb., 30 per cent. Films: Usual changes. Fract. test-meal: No free HCl.

Treatment: Liver diet; arsenic by mouth.

Feb. 15th, 1927: R.B.C., 2,500,000; Hb., 58 per cent. September, 1927: R.B.C., 5,000,000; Hb. 90 per cent. Films normal. Spleen not palpable. Fract. test-meal: No free HCl.

CASE 5.—Mrs. I. J., aged 48. March 13th, 1928: Anæmic many years. Two attacks of (?) jaundice a year ago. Typical appearance, very weak, appeared to be dying.

Blood: R.B.C., 730,000; W.B.C., 2400; Hb., 17 per cent.; index, 1·16; nucleated red cells, 20; reticulocytes, 7·8 per cent. Well-marked poikilocytosis, little punctate basophilia.

Treatment: Liver diet.

March 17th, 1928: R.B.C., 1,938,000; W.B.C., 3200; Hb., 25 per cent.; nucleated red cells, 13; reticulocytes, 12·8 per cent.

Treatment changed to Oxo liver extract. Fract. test-meal: Absence of HCl. March 23rd.: Hb., 42 per cent.; R.B.C., 2,463,000.

CASE 6.—Mr. K. L., aged 45. Nov. 15th, 1927: No sore tongue. Profound anæmia which had developed insidiously during the four previous years. Spleen not palpable.

Blood: R.B.C., 1,800,000; W.B.C., 7600; Hb., 30 per cent.; index, 0·83. Well-marked poikilocytosis, but nothing else abnormal.

Treated on liver diet, and made a rapid recovery.

This is clinically a doubtful case of pernicious anæmia. The man worked with chemicals and it was thought that his anæmia might result from chronic poisoning.

CASE 7.—Mr. M. N., aged 62. Lymphatic leukæmia, 1927.

Treated with large doses of benzol while abroad, and returned home with leucopenia and intense anæmia of aplastic type.

Liver diet had been taken steadily for three months without improvement, and liver extract for two weeks has had no effect.

SIX CASES TREATED AT THE GENERAL HOSPITAL, WOLVERHAMPTON.

Reported by S. C. DYKE, D.M., M.R.C.P.,
CONSULTING PATHOLOGIST TO THE HOSPITAL.

—	Cases treated with—		
	Liver diet only.	Liver extract only.	Both.
Apparently cured ..	3	1	2
Improved but relapsed ..	—	—	—
Failed to respond at all ..	—	—	—

Replies to Questions.

Dose of Whole Liver.—Following the advice of Minot and Murphy a dose of ½ lb. liver was given daily at the commencement of treatment. When the blood picture approached the normal the daily dosage was dropped to ¼ lb., and later yet in the treatment to 4 oz. three times a week. This amount was found sufficient to keep the blood count at a fairly normal level in most of the patients. If it showed signs of dropping the liver was increased, and in every instance where this was done the response of the red cells was quite satisfactory. In using extracts of liver a dosage was given equal, according to the makers' specifications, to ½ lb. of whole liver daily.

Patients treated on whole liver were put upon the following diet, arranged by Sister D. Roberts, to whom my thanks are due for this and for her success in overcoming the initial repugnance of several of the patients to the raw liver.

Breakfast.—One egg; dry and crusty bread, with butter to taste (not more than two rounds); tea or coffee (plenty of milk, sugar sparingly).

Lunch.—3 oz. of raw minced liver (made into sandwiches), sauce may be used for flavouring; an orange.

Dinner.—2 oz. of lightly cooked liver; 3 oz. of meat (if desired); 4 oz. of cabbage.

Tea.—2 oz. of lettuce; bread and butter (two rounds); one orange; tea.

Supper.—3 oz. of liver, as thick soup (flavoured with vegetables); 3 oz. of greens, Bovril.

Extracts Tested.—Two forms of liver extract were used in the course of the investigations—Hepatopson, a powdered preparation, and Liver Juice (Oxo). Both appeared to be effective in raising the blood count and keeping it up. In the one case treated from the beginning on Hepatopson the response was rather slower than in those cases treated on the whole liver, but when it came was quite satisfactory. Owing to the fact that until lately no liver juice was generally available other than that controlled by the Medical Research Council no case has been tried on a liquid preparation alone.

Simultaneous Treatment.—One patient, first seen with hæmoglobin 18 per cent., red cells 870,000 per c.mm., received a transfusion of blood which raised the hæmoglobin to 25 per cent. and the red cells to 1,470,000 per c.mm. The blood was taken from a patient suffering from polycythæmia and having a red cell count of 10,000,000 per c.mm. Although the desperate condition of this patient made it appear probable that nothing short of the transfusion could have saved him it is possible that he might have done without it, as in a further case first seen with 18 per cent. of hæmoglobin and only 650,000 red cells per c.mm., and in whom the initial condition was even worse, treatment was carried on by liver alone and the patient made a good recovery. In two cases septic teeth were removed. No other treatment apart from the administration of liver was used. Several of the patients had been on arsenic and hydrochloric acid by mouth, but this was stopped before the commencement of liver feeding.

Case of S.C.D.

CASE 17.—Male aged 50. Four years' history of increasing weakness with constant burning pains in the legs, particularly the right. On admission, Feb. 4th, 1928, he showed characteristic disturbances of sensation and alterations of the reflexes in both legs, particularly in the right, priapism at night, tingling in hands. Blood picture: Hæmoglobin, 68 per cent.; red cells, 4,570,000 per c.mm.; colour-index, 0·74; white cells, 8000 per c.mm. Differential count: Polymorphs, 67 per cent.; lymphocytes, 16 per cent.; monocytes, 7 per cent.; eosinophils, 10 per cent. Fractional test-meal showed complete absence of free hydrochloric acid. Patient was tried with the liver diet for three weeks, at the end of which time his blood picture and general condition showed no change. Discharged unimproved.

Cases of Secondary Anæmias.

CASE 10.—Profound anæmia of many years' duration with low colour-index and absence of morphological changes in the red cells, occurring in a female aged 53. The patient adhered to the diet well but without improvement.

CASE 11.—Anæmia following purpura in a diabetic patient, no benefit.

CASE 12.—Anæmia associated with tuberculous peritonitis, no benefit.

CASES 13, 14, 15, 16.—Anæmia associated with gastric disturbances, "gastric ulcers" absent at operation, dyspepsia and so forth, no benefit.

Cases of Aplastic Anæmia.

CASE 8.—Female aged 32. History of 12 months' bleeding from gums and susceptibility to bruising. Three days previously severe epistaxis. On admission, May 31st, 1927: Hæmoglobin, 21 per cent.; red cells, 930,000 per c.mm.; colour-index, 1·16; white cells, 1500 per c.mm. Differential count: Polymorphs, 46 per cent.; lymphocytes, 50 per cent.; monocytes, 4 per cent; platelets, 5000 per c.mm. No morphological abnormalities of red cells. Between the date of admission and June 10th, 1927, this patient was given six infusions of blood by Dr. Phyllis Grainger, house physician to the hospital. She was placed on the liver diet and this was persisted with for two weeks between two of the transfusions. During this time the hæmoglobin dropped from 25 to 20 per cent., and the red cells from 1,730,000 per c.mm. to 1,020,000 per c.mm. As the patient found the diet nauseating and it was obvious that it was doing no good it was then dropped. After a further transfusion, which raised the hæmoglobin to 27 per cent. and the red cells to 1,460,000 per c.mm., the patient was sent home and died six weeks later.

CASE 9.—Accurate notes not available. Female aged 16. Three months' history of susceptibility to bruising and bleeding from gums and nose. Admitted in a condition of profound anæmia, with marked diminution of platelets. Two infusions of blood were given and the patient was placed on the liver diet. She found this nauseating and, as in the previous case no benefit resulted, it was not continued. Death occurred after the patient had been in the hospital for one month.

Achlorhydria.—Not investigated.

Comments.

The reticulocyte count constitutes a very important means of ascertaining early whether or not a given case will respond to the treatment. A rise in the

proportion of reticulocytes to red cells occurs within three days of the commencement of treatment in cases responding satisfactorily. A fall in the serum bilirubin is also an early manifestation of improvement and would probably serve as well as the reticulocyte count as an indication of response to treatment.

Symptoms referable to the alimentary tract were prominent in five of the six cases; these symptoms comprising abdominal pain, vomiting, and anorexia all disappeared in every case early in treatment. Two of the six patients complained of dimness of vision and one showed irregular movements of the eyes which had led to a diagnosis of nystagmus. These ocular symptoms disappeared in both cases with the treatment. Four cases complained of symptoms, such as weakness of the legs and numbness and tingling of the hands and feet referable to cord lesions. In every case these symptoms remained after the blood picture had been rendered normal and the patient was in every other way well. In no case were these symptoms sufficiently severe to interfere with the patient's return to his work.

Liver in some form or other is specific for pernicious, Addisonian, or regeneratory anæmia. It is usually efficacious whether given whole or in the form of a suitable extract. No additional treatment other than symptomatic is necessary. Treatment by liver appears to have no effect upon aplastic or aregeneratory anæmia nor upon secondary anæmias.

TWENTY-FOUR CASES TREATED AT THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.

Reported by J. C. SPENCE, M.D., M.R.C.P.,
ASSISTANT PHYSICIAN AND CHEMICAL PATHOLOGIST TO THE INFIRMARY.

IN November last I reported [1] the results of the treatment of 20 cases of pernicious anæmia with the liver diet of Murphy and Minot. Since then I have had four more cases under treatment, making a total of 24 cases. In four of these cases a liver extract was used for the first few weeks of treatment. It was not possible to continue the extract until a complete cure was achieved, and after the initial trial of the effect of the extract the subsequent treatment in these four cases was carried out by means of a liver diet.

Replies to Questions.

Dose of Whole Liver.—My experience is, that if the improvement is to be maintained, the patients should eat at least two pounds (2 lb.) of liver a week. The liver may be lightly cooked without losing its effect.

Extracts Tested.—Four cases were treated with liver extract, using a daily dose equivalent to ½ lb. of fresh liver daily. It is not possible to compare these results with those of treatment by eating liver itself as the extract was used for a much shorter period. But so far as the efficacy of the extracts could be judged by their power to provoke a "reticulocyte crisis," it was shown that the extracts were therapeutically active, but not to the same degree as liver itself. That is, it required a dose of extract obtained from more than 1 lb. of liver to produce an effect equivalent to that half pound of lightly cooked liver itself. This would denote that in the preparation of the extract more than half of the effective material of the liver was lost.

Simultaneous Treatment.—In eight of the cases no other treatment of any kind was used; they responded as readily as those receiving hydrochloric acid.

One case of *aplastic anæmia*, a boy aged 8 years, was treated. His erythrocyte counts for two weeks before treatment fell gradually from 1,200,000 to 950,000. He was given 1 lb. of liver daily for one week and then ½ lb. daily for the next week, and later ½ lb. on alternate days. The treatment had no effect in the course of the disease, and he died ten weeks later. No post-mortem was obtained.

Achlorhydria.—In three cases the stomach contents were re-examined after intervals of three, five, and six months. In each the achlorhydria persisted.

Comments.

Of some of the patients who have been under treatment for more than six months, it cannot be said that they are completely cured, some anæmia with red cells from 3–4 millions being present, but in these cases it has been found that they have not been taking the liver diet satisfactorily.

One of the difficulties that has arisen is that patients eating liver tend to develop gout or arthritis, but this has not been noted when only the liver extract has been used.

SEVEN CASES TREATED AT THE MATER MISERICORDIÆ HOSPITAL, DUBLIN.*

Reported by Prof. HENRY MOORE, M.D., D.Sc.,
VISITING PHYSICIAN TO THE HOSPITAL.

SIX cases of pernicious anæmia have been treated with liver diet and one with liver extract (obtained from Messrs. Lilly and Co., Indianapolis, U.S.A., through the courtesy of Dr. Minot) according to the directions of Minot and Murphy. Of the seven cases two suffered from subacute combined degeneration of the spinal cord. All cases had a blood picture of pernicious anæmia and complete achlorhydria, as judged by the fractional test-meal. In each case, in addition to the liver diet or extract, 1 drachm of dilute hydrochloric acid (B.P.) and gr. 1 of pepsin (Parke, Davis and Co.) in a suitable mixture were given thrice daily after food, but no other treatment was used. The liver was always given cooked.

In five cases without nervous symptoms (other than paræsthesia in one) a remission occurred within three weeks of starting the treatment, as judged by the blood examination and clinical condition; improvement in the blood picture, appearance, comfort, and strength of these patients was evident within ten days or less and the remission has remained complete up to the present time, the treatment being continuously carried on. (See table.) Of the two cases of subacute combined degeneration of the spinal cord there was considerable nervous involvement and

		After.	4660	95	5800	

* The pathological work in these cases was done by Dr. A. R. J. Dungan, pathologist to the hospital.

only a moderate anæmia in one (Case 6), and in this patient neither the nervous symptoms and signs nor the anæmia showed improvement, although the appearance and the general condition was improved; in the other (Case 7, liver extract) the moderate anæmia gave place to a complete remission, the rather marked nervous manifestations improved, and the general condition was markedly benefited during the 33 days of observation. In the last-mentioned patient (Case 7) paræsthesiæ of the hands and feet, which were troublesome before treatment, are now no longer felt; the gait, which was markedly ataxic, has become almost normal; and Romberg's sign, which was marked, has almost disappeared; on the other hand, vibration sense in the legs as well as the tendo calcaneus and knee-jerks are still absent.

The amount of liver ingested was 120 g. per day; the dose of liver extract was 7·5 g. per day (equivalent to 150 g. of fresh liver). At first the strict diet of Minot and Murphy was given in each case, but later the improvement was maintained by giving liver or liver extract alone in addition to an ordinary well-balanced diet.

One case was tested for disappearance of achlorhydria six months after a continuous remission had been established; the achlorhydria was still present and the pH of the gastric contents over a three-hour period showed no significant change as compared with the test before treatment commenced. Six patients showed a peculiar and rather pronounced ruddy complexion after the remission appeared as compared with the sallow complexion previously present. In six cases the glazed redness and furrowing of the tongue was much improved by the treatment, but atrophic papillæ were probably not restored to normal.

Summary of Results.

Put briefly, five cases of pernicious anæmia have been markedly benefited by the Minot-Murphy treatment and have maintained this improvement while still carrying on the treatment over 17, 15, 14, 12, and 11 months respectively; points of interest in these cases are the ruddy complexion of the face and the rather high red cell count and hæmoglobin content which were found when the remission was complete. One case with severe nervous symptoms benefited to a much less degree during a period of six weeks' treatment and one, also with obvious nervous involvement and treated by liver extract, had a complete remission within the month of observation. The latter two cases had signs and symptoms of subacute combined degeneration of the spinal cord and, in the former, the nervous condition showed no change, but considerable improvement in the signs and symptoms of cord degeneration was observed within 33 days of starting treatment in the latter. The case observed for 17 months still complains, as at first, of paræsthesia of the hands and feet, but this symptom is now much less troublesome than before treatment—apparently the progression of the degeneration of the spinal cord has in this patient been, so far, prevented.

Several cases of secondary anæmia of various kinds but not due to hæmorrhage were treated with liver diet, but no striking results were obtained.

FOUR CASES TREATED AT MERCER'S HOSPITAL, DUBLIN.

Reported by Prof. L. ABRAHAMSON, M.D., F.R.C.P.I., PHYSICIAN TO THE HOSPITAL.

Of four cases of pernicious anæmia treated with liver diet three are apparently cured. The patient who died was moribund when seen and was unable to keep the liver down. No patient relapsed, but the liver is being taken still. Dose employed: 6 oz. per day. No simultaneous treatment, except that the patient has taken 15 minims of dilute HCl as well as the liver. This drug, along with iron and arsenic, had produced no improvement previously. The cases were typical in every way. In one case the red cells numbered 740,000 per c.mm. One case of severe secondary anæmia, in which the cause (uterine) had been removed, showed no improvement on liver. No evidence of disappearance of achlorhydria. Apart from the liver, no special diet was given. The liver was given in any way the patient desired, as a rule fried or grilled.

Public Health Services.

HOP-PICKERS' CAMPS: THEIR SUPERVISION AND SANITATION.

THE meeting and discussion arranged by the Royal Sanitary Institute on April 13th, appropriately at Maidstone, were concerned with the health of hop-pickers and the sanitation of the encampments they occupy during the few weeks of the hop-picking season.

The subject, introduced by a timely paper from Dr. Alfred Greenwood, medical officer for the county, is one which has exercised in an increasing degree the watchful anxieties of the health authorities for years past, and the general public has, until lately, probably been little aware of the difficulties which have had to be contended with to secure reforms in the conditions urgently calling for attention and remedy among the thousands of hop-pickers annually brought into the county from the poorest areas of south and south-east London and constituting an undisciplined host of between 70,000 and 100,000, mainly women and children. The arrangements, or the lack of them, in the majority of encampments attached to the hop-fields were for many years truly deplorable and a source of real danger alike to hop-pickers and residents in the vicinity, from overcrowding in the huts and the want of adequate latrine accommodation or decent provision of even elementary sanitary precautions. As evidence still fresh in the memory may be cited the severe epidemic of typhoid fever at Maidstone in 1897, traced to stream pollution from a hop-pickers' camp, and the risk of a similar occurrence is yet present. It is a matter of much concern and no little discredit, as Dr. Greenwood revealed in his paper, that measures of reform are still needed in quite a number of encampments at the present day. His disclosures come at an opportune moment, well in advance of the hop-picker's arrival, with time yet to ensure that the by-laws, too often honoured in the breach than the observance, may be successfully enforced during the coming season.

Encouragement is, however, to be found in the fact that as compared with the past there is now a good nucleus of hop-growers who have made a real study of the welfare of the hop-pickers in their employ and have achieved a great deal towards the provision of satisfactory accommodation, sanitation, and water-supply for the encampments, in some instances even beyond the requirements of the by-laws, and including personal attention to the need for treatment in cases of sickness and accident. These are, however, in a decided minority and there is no avoiding the evidence that conditions still exist in many of the encampments which are the very reverse of satisfactory, due maybe in part to apathy and indifference of the hop-growers themselves, in part to the too lax administration of the by-laws by the councils responsible in certain districts, the machinery for enforcing which, Dr. Greenwood pointed out, exists, but is not made use of to avert overcrowding and to ensure proper sanitation in the camps. By way of remedy it was suggested that future legislation should include camp registration and the issuing of licences only to those hop-growers who were able to satisfy the authorities concerned that the accommodation and sanitary conditions were adequate. It was further proposed that there should be a joint controlling committee of the Ministry of Health in collaboration with representatives of the local councils, boards of guardians, and voluntary organisations, which at present act independently of each other.

In addition the steady if gradual education of the poorer classes in matters of rudimentary hygiene and sanitation should be aimed at as a means of assisting the desired improvement. In this connexion the coöperation of the South London borough medical officers and health visitors might with advantage be enlisted for health instruction in the home of the hop-picker, preparatory to the exodus to the hop-fields At present matters are left too much to chance and the personal ideas of some of the hop-growers as to what will barely suffice. There is little doubt that efforts to secure reform by the health authorities have in some districts met with strong opposition, even abuse, through the stubborn obstacles of vested interests, obstructive control of the local press, and the apathy of district councils, in the face of which the medical officer's task has been no enviable one. Memories of camp life during the war recall to the sanitary officer the formidable difficulties attending the carrying out of sanitary measures, particularly among our Allies in the Near East. There was, however, the provision of a working squad to be relied upon and disciplinary power to act. In the case of the hop-pickers' encampments, the institution of a sanitary squad might be a step in the direction of improving the camp hygiene.

In helping the solution of the problem of treatment for the many cases of sickness and accident, which inevitably occur among the large numbers of hop-pickers each season, a great debt is owing to the voluntary organisations and private effort of individuals. Notably is this so at Marden, some ten miles from Maidstone, where, thanks to the unceasing energy and generosity of Mr. and Mrs. J. A. Spender, the Hop-pickers' Hospital with 11 beds and a medical centre was opened in 1924 and has since proved an immense local boon during the hop-picking season. No fewer than 3021 cases were treated by the staff of two lady medical officers and nine sisters and nurses last season. The cases included many severe burns, various accidents, 17 cases of pneumonia, and a few of infectious disease. Thirty-four were admitted as in-patients during the four to five weeks and 20 were transferred to London and local hospitals. It is certain, however, that similar centres are much needed in other districts.

The Ministry of Health has been actively concerned in the question of securing reform of the hop-pickers' encampments and in 1925 instituted an investigation of their state, which resulted in a special report by Dr. A. C. Parsons. It is therefore to be hoped that the further ventilation of the subject at the recent meeting at Maidstone will stimulate the active coöperation of all the authorities concerned to secure a considerable measure of improvement, and the attainment of a satisfactory standard of camp accommodation and sanitation in the districts where most needed.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 14TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week :—Small-pox, 321 (last week, 318) ; scarlet fever, 1646 ; diphtheria, 1117 ; enteric fever, 57 ; pneumonia, 1533 ; puerperal fever, 49 ; puerperal pyrexia, 120 ; cerebro-spinal fever, 8 ; acute poliomyelitis, 2 ; acute polio-encephalitis, 4 ; encephalitis lethargica, 33 ; dysentery, 60 ; ophthalmia neonatorum, 118. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 21 counties: London, 7 ; Bedford, 3 ; Derby, 10 ; Dorset, 1 ; Durham, 80 ; Essex, 4 ; Gloucester, 1 ; Kent, 1 ; Lancaster, 35 ; Leicester, 1 ; Lincoln, Parts of Lindsey, 8 ; Norfolk, 2 ; Northumberland, 9 ; Nottingham, 11 ; Salop, 1 ; Stafford, 4 ; Warwick, 4 ; Yorks, North Riding, 3 ; West Riding, 100 ; Glamorgan, 17 ; Monmouth, 19.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on April 17th–18th was as follows : Small-pox, 11 under treatment, 3 under observation ; scarlet fever, 1550 ; diphtheria, 2288 ; enteric fever, 34 ; measles, 1535 ; whooping-cough, 146 ; puerperal fever, 16 (plus 14 babies) ; encephalitis lethargica, 66 ; "other diseases," 26. At St. Margaret's Hospital there were 13 cases of marasmus, and 13 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (0) from enteric fever, 143 (82) from measles, 4 (1) from scarlet fever, 45 (16) from whooping-cough, 39 (8) from diphtheria, 38 (12) from diarrhœa and enteritis under two years, and 85 (9) from influenza. The figures in parentheses are those for London itself.

Of the 61 fatal cases of measles outside London, 6 were reported from Sheffield, 5 each from Croydon and Tottenham, and 4 each from West Ham and Walthamstow, while the figures in Edinburgh, Glasgow, and Dublin for the same week were 2, 5, and 3. Of the 29 fatal cases of whooping-cough outside London 11 were reported from Liverpool.

The number of stillbirths registered during the week was 329 in the great towns, including 48 in London.

MEDICINE AND THE LAW.

Coroner and Medical Status.

THE death within a few minutes of admission to St. Giles Hospital, Camberwell, of a patient transferred by ambulance from Guy's Hospital, has given rise to some correspondence between the coroner for South London, who conducted the inquest, and the House Committee of Guy's. The patient, when still conscious, was seen at Guy's by a house surgeon, and diagnosed as cerebral hæmorrhage, but since only one bed was available, arrangements were made for the admission of the patient elsewhere. The autopsy showed that death was due to an extensive cerebral hæmorrhage ; in the opinion of the doctor who performed it, the patient would have died in any event, but the jolting of the ambulance would intensify the hæmorrhage. The jury returned a verdict of death from natural causes, absolved the house surgeon from blame, but considered that a system whereby patients were transferred from one hospital to another on the opinion of one doctor, "and that a junior house officer," was "gravely unsatisfactory," and suggested that two resident medical officers should see the patient and sign the removal papers. They desired that their opinion should be notified to the hospital authorities and the coroner, in forwarding the message, spoke of "regrettable occurrences of this kind."

In a considered reply the hospital authorities note and concur with the view that no blame attaches to the house surgeon ; they strongly dissent from the implication of the second part of the rider, that the coroner or any other legal authority has the right to decide whether this or that medical practitioner is qualified to perform any particular medical service or operation. Their position is that if a duly qualified practitioner examines and treats a patient with proper care, he should not be criticised on grounds of juniority or of his particular medical qualification. His competence is vouched for by the General Medical Council. The fact that most careful consideration of the qualifications of a candidate precedes his appointment to the coveted post of house officer is mentioned, though in our opinion this fact is not directly relevant to the question at issue. The suggestion that two hospital medical officers should have to sign removal forms would discriminate unduly between them and practitioners outside the hospital who have frequently to decide to transfer patients from their homes to institutions. Moreover, transference from one to another institution may be desirable when the case is in no way acute or dangerous. The House Committee show how

nconvenient and oppressive in many directions would be the results of adopting the recommendation made. The profession would, we agree, object to such a limitation being put upon the discretion and responsibility of individual practitioners.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Recent Research on the Vitamins.

THE Committee on Nutritional Problems of the American Public Health Association publish in the current journal a report that is not merely a supplement to but in some sense a revision of their report published six years ago. The main advances of the intervening years have been made not so much in the pure chemistry of the vitamins as in the knowledge of their nutritional relationships, their significance to health, and their distribution among food materials. New vitamins have been recognised: fat-soluble D, or the antirachitic vitamin; fat-soluble E, the vitamin of reproduction, and the two parts of vitamin B. The committee propose that these two parts shall be separately named F and G, leaving B as the name for the "complex," which may contain several other factors. F, they say, will be readily associated with the name of Funk, who has been a pioneer in the recognition of the antineuritic substance, and G with the name of Goldberger, who believes this factor to be preventive of pellagra. (It has often been written PP in the literature of this country.) The committee point out that the popularity of vitamins has led to commercial exploitation. There is at present no standardisation of the numerous preparations sold at high prices through the drug trade, and claiming to contain one or more of the vitamins in more or less concentrated form. While physicians may occasionally have use for such preparations, "the public will find it much safer and more economical to obtain vitamins as normal constituents of a wisely chosen food supply than from the drug store, whether in the form of pills, powders, or extracts." On the other hand, the committee are not impressed by those who claim that the average man gets plenty of vitamins and to spare. The optimal intake of vitamins is apparently, in view of recent investigations, many times greater than the amount necessary to protect us from manifest deficiency disease. One may take too many calories, but not, it seems, too many vitamins. It is necessary therefore to choose food with care and to guard the vitamins in our raw material from needless destruction by the cook.

Vitamin A.

Xerophthalmia is not the only ill-result of a deficiency in vitamin A. The principal change found in rats suffering in various degrees from this deficiency is "transformation of various epithelia into a stratified squamous keratinising epithelium. This change is practically constant in the upper respiratory tract, including the whole of the nasal passages, larynx, trachea, and bronchi." Vitamin A is regarded by the committee as more seriously neglected in our diet than any other vitamin. This on several grounds: so many staple foods are poor in the vitamin; its deficiency results in such a variety of damage to the human organism, and the differences in food habits which closely affect the health and longevity of the public are so familiar as to be regarded with indifference. The capacity for and the importance of storage of this vitamin are emphasised in recent research. This is an additional argument in favour of ingesting all the vitamin A that a wise choice of foodstuffs can supply. It has been shown that a supply of vitamin A which is sufficient to support normal growth and maintain every appearance of good health for a long time may yet be insufficient to meet the added demands of reproduction and lactation. The committee lay stress also on the increased susceptibility to pulmonary infections which results from deficiency of this vitamin, pointing out (1) that the breakdown occurs at the age corresponding to that at which pulmonary tuberculosis so often becomes manifest in man, and (2) that the content of vitamin A in pulmonary tissues varies directly with that in the food ingested. The vegetable sources of this vitamin can be well recognised from the parallel occurrence of chlorophyll. Of animal sources milk is probably the most important. The committee repeat a former recommendation that one quart daily for children, and one pint daily for adults is a minimal allowance. Liver is the best flesh food from the point of view of vitamin A, since it is in the liver that storage chiefly takes place. A varying amount of the vitamin is also found in adipose tissue. Heating at reduced acidity or slight alkalinity (about pH 9), which is very destructive to B and C, is almost without effect on A, and in general it may be said that this is a stable vitamin and can be relied on to retain its virtue despite the culinary processes of civilised living. Further reports are promised on the other vitamins.

CO as an Industrial Hazard.

While your Government is inquiring into the danger of lead ethyl, our public health service is investigating another older and probably greater hazard of the motor industry, the risk of carbon monoxide poisoning from exhaust gases. The risk of running the engine in a small closed garage is well recognised, and yet each year as the cold weather comes on our newspapers are filled with tragedies resulting from this very cause. The evil, however, appears to exist in larger garages, and even to some extent in the streets of our largest cities without arousing suspicion, or leading to due precautions. The accepted standard of risk in this country is that laid down by Prof. Yandell Henderson of Yale during the calculations made for ventilating the new traffic tunnel beneath the Hudson river from New York to New Jersey. Dr. Henderson pointed out that the risk is a product of the time of exposure and the concentration of the gas, and expresses the degree of risk in the following formulæ where "t" is exposure in hours, and "c" concentration of CO, in parts per 10,000:—

$t \times c = 3$	No perceptible effect.
$t \times c = 6$	A just perceptible effect.
$t \times c = 9$	Headache and nausea.
$t \times c = 15$	Dangerous.

Thus an exposure of 12 hours to a concentration of 1·2 parts per 10,000 or an exposure of eight hours to a concentration of 2 parts per 10,000 may be considered dangerous. That such exposures are not at all infrequent has recently been shown by J. J. Bloomfield and H. S. Isbell,[1] who made 250 analyses of air taken in 14 of the largest cities in this country. Of the samples taken in city streets 24 per cent. showed a concentration of more than 1 part per 10,000, but in only one case (under a covered passage way) was the concentration as high as 2 parts per 10,000. The chief risk here is to traffic officers, and it has already been shown that eight hours point duty may result in a carboxyhæmoglobinisation of 30 per cent. of the blood. The risk in garages, however, appears to be much greater. Here engines may be left idling while the "mixture" is varied in search of an optimal concentration. Such procedures often result in a very rapid rise of the CO concentration. The average of 102 samples taken in garages showed a CO concentration of 2·1 parts in 10,000, while 18 per cent. of the samples showed a concentration over 4 parts per 10,000. The investigators add that "had these tests been made during cold weather, no doubt the carbon monoxide would have reached higher concentrations."

In one repair shop a very simple ventilating device was in operation. A flexible hose was connected to the exhaust pipe and remained there while the engine was running. The exhaust gases were conveyed by a flue to the roof. The efficacy of the apparatus was tested and it was found that while it was retained the concentration did not rise above 0·7, but when the

[1] Public Health Reports, March 30th, 1928, p. 750.

engine was allowed to run for the same length of time without the hose connexion the garage air at mouth level was found to contain 2 parts per 10,000 of CO. It is recommended that no engine should be allowed to run in a repair shop for more than 30 seconds, except in driving in or out of the shop, unless some arrangement has been made for removal of exhaust gases. In practice probably the simplest legal restriction is that adopted by the city of Chicago, where the municipal code requires that the air of garages shall not exceed 2 parts of CO per 10,000 of air.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Dail and Compulsory Vaccination.

Mr. Everett, one of the deputies for County Wicklow, has introduced to the Dail a Vaccination (Amendment) Bill which, if passed, would render vaccination laws in the Irish Free State identical with those in England. Hitherto there has been no conscientious objection clause in the Irish law on vaccination. The Bill has received support from a number of members of all parties, although strongly opposed by the Minister for Local Government and Public Health. In opposing the second reading, the Minister (Mr. R. Mulcahy) said that there was no body of medical opinion in favour of the Bill, and that the official medical bodies had passed strong resolutions in favour of the existing vaccination laws. Their experience had been that the present Vaccination Act was justified, and that such modification as had been made in England had brought about the really disastrous position that at present existed in regard to small-pox. In any outbreak of small-pox in this country there was an additional danger in the fact that a very small percentage of their medical men had any experience of the disease. The Minister had the unanimous support of the medical deputies in the Dail, regardless of party.—Dr. P. J. O'Dowd said that the reason they had not small-pox in Ireland was because of the success of the compulsory vaccination clause.—Dr. V. White said that he could not see how the man in the street could acquire the scientific knowledge qualifying him to express an opinion on vaccination.—Sir James Craig said that they should do something to protect children who were not able to study the matter themselves and who would be the people to take small-pox if an epidemic broke out. They had been told there was a conscience clause, but the conscience clause had resulted in 15,000 cases of small-pox last year in England.

Death of the Medical Officer of Health for the City of Cork.

The death of Dr. J. D. Carroll, medical officer of health for the City of Cork, which occurred last week at the age of 38, is a loss not only to Cork but to the whole public health service of the Irish Free State. He was a man of exceptional ability and energy and was looked on as one of the most promising recruits to the public service in recent years. He had only been appointed to his office last year, but already had made his influence felt in many directions. Born in Dundalk and educated at Clongowes Wood College and University College, Dublin, Carroll took his medical degrees in 1913. He joined the Royal Army Medical Corps in 1914 and served in Gibraltar, Malta, Egypt, and France, where he won the Military Cross. After the war he took up public health work and served for some time as school medical officer under the London County Council. In 1922 he was asked to organise the sanitary work of the Free State Army. He held the post of chief sanitary officer until September, 1925, when he was awarded a Rockefeller Fellowship for the study of public health work in the United States. Personally, Dr. Carroll was held in great affection by all who knew him. As a gallant officer, as a sportsman, and as a man of science he had made his mark, and a great and useful future was expected for him.

"Audi alteram partem."

HAS THE CAMPAIGN AGAINST VENEREAL DISEASES BEEN A FAILURE?

To the Editor of THE LANCET.

SIR,—Mr. Johnston Abraham has very accurately put his finger upon one of the main weaknesses of the present scheme—viz., the extreme difficulty in adequately treating a person suffering from gonorrhœa. Such a patient must in treatment face much inconvenience, discomfort, tedium, and uncertainty. Undoubtedly the ideal treatment of gonorrhœa lies along in-patient lines; but in civil life this is, for obvious reasons, impracticable in the vast majority of cases. In my experience few syphilitics default while in the infectious stage. The urgent problem to be solved is the defaulter suffering from gonorrhœa.

The practical treatment of the disease must remain in the out-patient category, and this can be divided into two classes: (1) where the facilities available approximate in some degree to in-patient treatment, and (2) where they do not. Apart from actual confinement to bed the ideal out-patient treatment of gonorrhœa—in class (1)—is where the patient can be treated every day, several times a day, and at hours of his or her own choosing. Such facilities are not available in the V.D. section of the general out-patient department of the average hospital, and in consequence the results are unsatisfactory, the patient progresses but slowly and tends to become a defaulter. Where a clinic is held, say, on two days a week with intermediate treatment available daily for two hours, it becomes impossible, if patients are seen in any numbers, to give them that individual study, care, and attention, upon which success almost entirely depends. There is neither a sufficiency of time nor of staff to administer adequate treatment. This operates very hardly upon female cases. The routine in the municipal clinic of the city of Salford is that women receive intermediate treatment by the nurse, at least once daily, and in addition each receives treatment by the medical officer on alternate days. To tell the average female patient to douche at home or to provide the male patient with a syringe for home use, is merely putting into their hands ideal instruments for wreaking havoc in their genito-urinary passages. Without a tremendous amount of continuous hard work by M.O. and nurse the treatment of gonorrhœa in a V.D. clinic is almost futile. Enthusiastic devotion to the interests of the patient should be the keynote of the clinic. It is an institution that must place itself at the service of the patient. Where the occasional and part-time V.D. clinic is merely a side-line to the out-patient department of a hospital, the chief essentials for securing regular attendance of the patient and rapidity of cure are wanting.

While in full agreement with the efforts of the cities of Edinburgh and of Glasgow to secure some measure of compulsory power over the V.D. non-attender, I do consider that a great deal of defaulting can be combated by instituting, in areas where the population warrants, whole-time ad hoc clinics, which are open continuously for 12 hours daily. The ad hoc clinic, since it is worked by a whole-time staff specially trained in venereological methods, and is equipped for the sole purpose of diagnosing and treating venereal disease, is an institution placing itself at the entire disposal of the patient for 12 out of the 24 hours. It alone can make any approximation to in-patient methods of treatment. The stream of patients, instead of being concentrated into two or three hours on certain days, is distributed throughout the day and week. The result is that the individual receives a personal attention, impossible under the other system. The theoretical objection that patients are shy of attending an ad hoc clinic is not borne out by experience. They appear to prefer it.

But even the whole time ad hoc clinic cannot pull its full weight or turn out the best work unless it possesses sufficient beds. A certain number of these should actually be in the clinic, and not at some other institution. Money spent on proper in-patient accommodation is well invested. The minimum satisfactory arrangement consists in having bed accommodation for 10 per cent. of annual new patients. Half these beds should be at the clinic, and half at a hostel for the treatment of children and pregnant women.

The campaign has not failed, although it has not yet been completely successful. The attack is not finished nor is it exhausted. It can be reinforced in two ways: (1) by introducing an element of compulsion, and (2) the provision of whole-time ad hoc treatment centres in large cities to replace the part-time clinics at present attached to hospital out-patient departments.

I am, Sir, yours faithfully,

E. TYTLER BURKE,

V.D. Medical Officer for the City of Salford.

April 23rd, 1928.

To the Editor of THE LANCET.

SIR,—Mr. Johnston Abraham suggests that the answer to the question at the head of his letter is in the affirmative, but I venture to think that the official campaign as supported by the Ministry of Health has been successful to a limited degree in regard to syphilis, although it has failed (as it was bound to fail) in regard to gonorrhœa, which can easily be prevented in the male and so indirectly in the female; but once having developed it remains in an infective state for an indefinite period.

Mr. Abraham refers to the excellent "Statement for the Corporation," issued by the Edinburgh Public Health Authorities in February last, in connexion with the Edinburgh Corporation Bill, that was refused a second reading in the House of Commons on April 19th, by a majority of 63 in a House of 253. This statement (in para. 2) affirms "both syphilis and gonorrhœa are preventable diseases" and "both are curable if treated early and efficiently." As pointed out by Dr. J. H. Sequeira on many occasions in the past, the two aspects of the antivenereal campaign must not be confused, the first and more important being the public health infectivity aspect and the second, less important, aspect being that of the *cure of the individual*. The effect of preventive or curative measures on the period of infectivity and on cure must, therefore, be considered separately. It is axiomatic that if infection by a disease is prevented by any method of hygiene or disinfection the question of infectivity does not arise. If, however, the infection has not been prevented steps must be taken, first, to prevent the infection being passed on and to limit the period of infectivity as much as possible, and secondly to cure the infected individual.

As regards syphilis, these two desirable objects are secured by the administration of injections of arseno-benzol compounds, and the individual ceases to be actively infectious, certainly after three injections given at intervals of three days. The clinic system of free and efficient treatment has, therefore, been successful in very greatly reducing the incidence of syphilis. With gonorrhœa, however, the cure of obvious signs and symptoms of disease in the individual does not entail any even temporary absence of infectivity. The patient may feel perfectly well and exhibit no symptoms that cause him or her any uneasiness or anxiety whatever and yet may remain in an acutely infectious condition. It is not, therefore, astonishing that the clinic treatment system has failed in regard to gonorrhœa.

The speakers in the debate on the Edinburgh Corporation Bill who opposed the second reading rightly pointed out that it was impracticable to insist upon compulsory treatment until cure was effected, as there would be very wide divergence of opinion amongst medical practitioners as to when this point had been reached; but the opposers of the Bill apparently had not noticed that an alternative to cure had been given in the following words, which ran: "or until it has been certified that he is unlikely to cause infection." The words "continue such treatment until he is cured" could well have been struck out by an amendment, as the whole of para. (3), clause 3, dealing with detention in hospital had already been struck out. If it had been considered inadvisable in view of differences of opinion as to period of infectivity to permit the alternative mentioned above to remain, a minimum of treatment might have been made compulsory such as "one year's treatment for syphilis and three months' treatment for gonorrhœa." Although such a minimal course of treatment would not always be satisfactory, a considerable majority of cases of gonorrhœa would be rendered non-infectious, and the chance of even remote relapse to infectivity in syphilis would be small. I think the majority of infections with both syphilis and gonorrhœa result from intercourse with an individual who has not submitted to even such a minimal course of treatment.

It seems a matter for regret that the Bill was not given the opportunity of full discussion in Committee, as, though many of the objections raised by the medical opponents of the Bill were weighty, these objections might quite possibly have been met by amendments, and an Act put on the Statute Book which would have afforded a most valuable experiment under exceptionally favourable circumstances. Personally, I am of opinion that early and efficient treatment, whether voluntary or compulsory, will, in time, reduce syphilis to the position of a rare disease, but will never have any very marked effect on the diminution of gonorrhœa, which will only be achieved by the education of the male public in immediate self-disinfection after risk.

I am, Sir, yours faithfully,

H. WANSEY BAYLY.

Harley-street, W., April 23rd, 1928.

To the Editor of THE LANCET.

SIR,—I do not agree with Mr. Johnston Abraham's statement in your issue of April 21st (p. 834) in connexion with the treatment of gonorrhœa that we have nothing in our armamentarium comparable to arsenic in syphilis. Preparations of silver and permanganate of potash are as effective in gonorrhœa as arsenic is in syphilis so far as the respective micro-organisms are concerned. It is the technique of treatment that is at fault. By this I mean irrigation per urethram. I have found injection of the vas absolutely reliable in dealing with every stage of the disease. I am, Sir, yours faithfully,

Harley-street, W., April 23rd, 1928. J. F. PEART.

To the Editor of THE LANCET.

SIR,—Your annotation on venereal disease control (THE LANCET, April 21st, p. 821) in the light of Dr. J. H. Stokes's article and the possible help he might give us with regard to Edinburgh, if he would develop his experiences of "the strong arm of local public health officials," should, I think, be followed up.

I had the opportunity, about five years ago, of talking over these matters with several of the local public health officials in some of the important cities in America. I am inclined to think that the "strong arm of local public health" bears a relation to what Dr. Stokes speaks of as "inadequate follow-up." The syphilis clinic relies on two things: (1) social service, (2) the strong arm of the local public health officials. The results are, according to Dr. Stokes, that no higher proportion of patients can be kept under observation than from 20 to 40 per cent.

Compare this with Edinburgh, where, without the strong arm of local public health, they keep under observation and treatment 71 per cent. of the patients; or compare the results in Holland, where an entirely voluntary system is in practice. The Chief Medical Officer of Health for Amsterdam made the following statement in 1925: "At Amsterdam, thanks to the devotion of doctors, nurses, and the social worker

attached to the policlinic, we have obtained this remarkable result, that 95 per cent. of the syphilitic men and 85 per cent. of the women have remained continuously under treatment at the clinic and policlinic during the two years that this system of collaboration has been established. These figures are certainly not surpassed by those obtained in countries where compulsory treatment is in force."

It is probable, I think, that the American compulsory measures are really responsible for the "inadequate follow-up," for where it is known that compulsory measures *may* be used, there is a greater incentive for patients to give false names and addresses. It would seem, from results given above, that we may learn more from Holland than from America. I am, Sir, yours faithfully,

Oxford, April 24th, 1928. HENRY T. GILLETT.

INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—Having practised the injection treatment of varicose veins over a long period, we have read with interest the paper by Mr. Rodney Maingot and Mr. C. Hope Carlton in your issue of April 21st. Whilst appreciating their work in furthering the use of a new and approved treatment of varices, we find ourselves unable to agree with them upon certain details of technique.

Position of the Patient.—Except in the treatment of the smallest varices we have long abandoned the erect and sitting postures owing to the increased venous tension which they produce. We prefer to keep the patient completely recumbent, either prone or supine, and to inject the veins in the collapsed state which then exists. The technique is admittedly much more difficult when this position is adopted, but efficiency is rapidly acquired and the advantages are definite. In the first place, a smaller quantity of sclerosing fluid is required and it comes into intimate contact with the entire endothelial circumference of the vein, thus securing more certain irritation and sclerosis. Secondly, the tendency to bleeding and leakage into the tissues is reduced to a minimum; and finally, in dealing with nervous patients, the recumbent position causes less anxiety both to the operator and the subject.

Method of Inserting the Needle.—Unlike Mr. Maingot and Mr. Carlton, we get better results by piercing the varix directly than by entering the needle obliquely so as to produce a valvular opening in the vein. The secret of controlling leakage after injection is to apply firm digital pressure over the site of puncture, and when the aperture in the skin is situated directly anterior to that in the wall of the vein it is much easier to secure correctly directed pressure than when the apertures are at some distance apart. In any case, by employing direct puncture in treating all our varices the instances of pigmentation and ecchymosis which have been met with do not approach the average 10 per cent. reported by Mr. Maingot and Mr. Carlton. In our opinion it is not back-flow which provokes necrosis and ulceration, but paravenous injections and those made into bluish, superficial veins whose walls have been reduced to a mere pellicle; these unhealthy walls are unable to withstand the distension consequent upon the introduction of concentrated irritant fluids into their lumina.

Amount of Sclerosing Fluid.—After stating the quinine and sodium salicylate formulæ which they prefer to employ, Mr. Maingot and Mr. Carlton mention that "not more than 15 c.cm. should be given at one sitting." It is not clear whether this quantity of fluid is to be considered in terms of salicylate or quinine, but, if the latter, then it is easy to account for the instances of giddiness, fainting, tinnitus, and general abdominal pain which they place on record. 15 c.cm. of the quinine bihydrochloride solution mentioned represent an intravenous dose of roughly thirty grains of quinine. In treating a comatose malarial patient it is considered a heroic measure, faced with the risk of quinine poisoning, to administer fifteen grains of this drug intravenously, and we feel that in spite of the recognised alteration of the blood flow in varices, the authors have been fortunate in avoiding more serious toxic symptoms in patients who have received the maximal dose of thirty grains at a single sitting. Especially in using 20–30 per cent. concentrations of sodium salicylate we are accustomed to employ fairly large injection; but never, in employing Génévrier's quinine formula as quoted by Mr. Maingot and Mr. Carlton, have we found it necessary to introduce more than 5 c.cm. at one séance. Following the advice of A. H. Douthwaite we limit our primary dose of quinine to 1 c.cm. in order to test the susceptibility of the patient to the drug. More important, however, is it to examine the subsequent venous reaction, a phenomenon which varies remarkably in different individuals. In one case injection of 0·5 c.cm. of standard quinine-urethane solution caused the entire obliteration of a varix extending from the thigh to the ankle, with tenderness and reddening of the superficial tissues which lasted for a week. Although the varix was a large one we tremble to think of the consequences which might have ensued in this case if an injection of 5 c.cm. had been made. This case also shows the fallacy of the statement by Mr. Maingot and Mr. Carlton that the vein becomes "thrombosed to an extent which varies directly with the amount of solution injected."

We are confident that, however massive or vermiform the clusters of veins to be sclerosed, the process if it is to occur, will best develop after injections of a standard quinine-urethrane solution not exceeding 1 c.cm. introduced into one or more segments. Larger amounts are superfluous if not actually harmful.

We are, Sir, yours faithfully,

KATHARINE M. CELLAN-JONES, M.B., B.S.
C. J. CELLAN-JONES, M.D., F.R.C.S.E.

Swansea General and Eye Hospital, April 21st, 1928.

EPILEPSY IN DEMENTIA PRÆCOX.

To the Editor of THE LANCET.

SIR,—In his Lumleian lectures Dr. James Collier makes the statement that "epilepsy is of common occurrence in dementia præcox" (THE LANCET, March 24th, p. 589). I should be interested to learn the source of his authority in making this assertion. In my experience, fits of any kind are of the rarest occurrence in dementia præcox, and, in the event of their appearance, it is a wise precaution to reconsider carefully the original diagnosis.—I am, Sir, yours faithfully,

THOMAS D. POWER.

Brentwood Mental Hospital, Essex, April 18th, 1928.

TONSILLECTOMY AND RHEUMATISM.

To the Editor of THE LANCET.

SIR,—My letter was not intended to be critical or controversial. Dr. Wilkinson and Dr. Ogilvie expressed doubt as to the sufficiency of the number of cases investigated to allow of any definite conclusion and I performed for them the necessary arithmetic to test that numerical sufficiency; in other words, to see whether the variations disclosed are sufficiently large to be beyond the range of a reasonable expectation of chance variation. The usual statistical criterion of numerical sufficiency is the "probable error," an unfortunate but conventional name for the range of variation which is equally likely to be exceeded, or not to be exceeded, by errors of sampling or what might be termed a "run of luck." When I gave the difference and probable error of the difference in the fatality rates between the tonsillectomy cases and the non-tonsillectomy cases as $4{\cdot}6 \pm 4{\cdot}8$, it signified that it is as likely as not, on purely statistical grounds, that such a difference is merely a matter of chance. Only when a difference is three times its probable error is it regarded as significant according to the usual convention. The smaller the number of cases the greater is the probable error of the rate founded on them. Actually I agree with Drs. Wilkinson and

)gilvie that tonsillectomy is likely to reduce the everity of cardiac complications, but this was not the oint under investigation by me ; it was the statistical dequacy of the numbers adduced to support the ontention that I was investigating.

My rearrangement of Table IV. was due to the rithmetical discrepancy that the numbers given in he two right-hand columns do not tally with the otal number given in the left-hand column, the children ith glands but no tonsils having been excluded, and reproduce the table from your issue of March 31st.

TABLE IV.—*Rheumatic Children.*

Heart condition.	Healthy throats.	Tonsils and glands.
	Number and percentage.	Number and percentage.
ormal (27 cases) ..	20 (74)	6 (20)
amaged (20 cases)..	9 (45)	9 (45)
iseased (24 cases)..	8 (33)	15 (62·5)

The paraphrase of " normal tonsils " for " healthy roats " was inadvertent. I was led into this error ecause in Table V. the 37 children with " healthy roats " are described as having the throat condition normal." But my paraphrase has led to the isclosure of the fact, not revealed in Table IV., at a number of the children with " healthy throats " ad had their tonsils removed. It would now seem at the cases included under the rubric " healthy roats " consist partly of children who have normal nsils and partly of children who have had their nsils removed, presumably on account of tonsillar sease. As this group is not homogeneous it is not ossible to draw inferences from it in the manner that attempted.

I fear that the conclusion must be on the usual atistical criteria that, though suggestive, the mbers of cases are insufficient to be beyond the ach of variations due to chance, however strong e clinical grounds may be for belief in the value tonsillectomy in rheumatic cases.

I am, Sir, yours faithfully,

C. O. STALLYBRASS,

April 21st, 1928. Asst. M.O.H., City of Liverpool.

UTANEOUS AND VISUAL HALLUCINATIONS IN THE CHRONIC HALLUCINATORY PSYCHOSIS.

To the Editor of THE LANCET.

SIR,—In connexion with the article by Dr. acnamara in your issue of April 21st it may be of some terest to mention a case of a similar kind which me under my notice at the Maudsley Hospital. is patient, like those of Dr. Macnamara, was a oman who had passed the menopause, and her skin nsations and the hallucinations and delusions sing therefrom were subject to marked fluctuations cording to the state of her general health and of the eather. She showed some evidences of thyroid ficiency, and under thyroid administration her skin came less dry and scaly, less sensitive to cold, and s irritable ; this seemed to react upon her mental ate, and although she never completely lost her lief that she was infected with vermin, it became ich less prominent and affected her conduct and otional state to a much slighter extent, so that she came more cheerful, and was able to resume social ntacts and her occupation of teaching music.

Since these patients are mainly elderly or middle-ed women it seems possible that thyroid and ovarian retions are deficient, causing dryness, scaliness, and itability of the skin which act as the basis upon ich hallucinations and delusions are formed ; the se mentioned above suggests that it is at least rth while to try the effect of glandular therapy on such patients.

I am, Sir, yours faithfully,

Lincoln, April 20th, 1928. MARY R. BARKAS.

SUBLINGUAL ABSORPTION OF MORPHINE.

To the Editor of THE LANCET.

SIR,—In an annotation in your last issue reference is made to the sublingual method of administration of morphine sulphate. It is stated that Dr. David Davis and Dr. David Ayman suggest the discontinuance of administration of the drug by this route. I have been using this method for many years successfully by simply placing a crusted tablet under the tongue, but I powder it first in cases of deficient salivation. Absorption by the sublingual gland takes place rapidly and the effect of the drug is satisfactory. I am employing the sublingual method with all the alkaloids almost exclusively in my practice, making use of hypodermic injections principally for the induction of local anæsthesia in surgical operations. If a patient accidentally swallows the tablet I repeat the sublingual administration. Much time is saved by this method, and asepsis is assured. Many years ago I published [1] my experience of the sublingual method, illustrating my remarks with selected cases. In one case—poisoning by carbolic acid—where swallowing movements were absent and the patient was moribund, the administration of apomorphine by the sublingual method produced vomiting. Whatever may be the explanation of the American findings I shall continue the sublingual practice with which for many years I have been highly satisfied.

I am, Sir, yours faithfully,

A. P. MURTZ.

Queen's-road, Finsbury Park, N., April 21st, 1928.

INVESTIGATION OF MATERNAL MORTALITY.

To the Editor of THE LANCET.

SIR,—The Council of the Society of Medical Officers of Health has had before it the letter appearing in the *Times* of April 3rd, over the signatures of certain obstetricians, as to the need for research into the above subject. The Council is in agreement that the research required calls for a close alliance between the physician, the biochemist, and the bacteriologist, and the close apposition of the laboratory to the bedside, but it is not of opinion that an investigation by local health authorities of all maternal deaths should be excluded or discredited, and the Council regrets that the signatories have seen fit to take this view.

The Council would further put on record that the signatories are in error in suggesting that a knowledge of the cause of a disease is necessarily a sine qua non for its prevention, and in this connexion would refer to the control of small-pox by vaccination ; the diminished incidence of enteric fever following on the betterment of sanitary and living conditions ; and the reduction of deaths from scarlet fever as the result of the measures taken by health authorities.

The Council of this Society feels that matters of this kind are best discussed in the professional journals.

I am, Sir, yours faithfully,

E. H. SNELL,

Acting President, Society of Medical Officers of Health.

1, Upper Montague-street, W.C., April 24th, 1928.

*** It is noteworthy that in Circular 888, issued this week by the Ministry of Health to local authorities, attention is called to a previous circular recommending an investigation in every area by an experienced medical officer of all maternal deaths and all cases of puerperal fever. The Minister regrets to learn that such inquiries have, so far, been adopted in very few areas, possibly because it has not been apparent to local authorities what practical results might follow. The Minister explains that the object is to obtain and study a mass of properly classified information as to the causes of death in a large number of cases, and to this end a Maternity Mortality Committee is to be set up at the Ministry. This

[1] Practitioner, 1916.

Committee will draw up a questionaire to serve as a guide in making the investigation, in order to secure uniformity of methods, will collate the information received from this and other sources, and will make suggestions as to further research or action. —ED. L.

APPEAL FOR SPONTANEOUS TUMOURS FOR STUDY.

To the Editor of THE LANCET.

SIR,—My researches have now come to a stage at which I can determine at will the regression of either implanted rat sarcoma, or carcinoma, by means of vaccine treatment. The rats so treated are thereafter immune to reinoculation with the tumour concerned. In order, if possible, to make further progress it is essential to discover whether similar results can be obtained with the spontaneously occurring tumours of mice, rats, guinea-pigs, rabbits, cats, or dogs. May I through your columns appeal to those who possess them to be so good as to send any tumour-bearing animals *alive* to me at the Lister Institute, London, S.W. 1. I will gladly pay any expense involved.

I am, Sir, yours faithfully,

April 18th, 1928. THOMAS LUMSDEN.

Obituary.

CHARLES GREENE CUMSTON, M.D. GENEVA.

IT is with great regret and a real sense of loss that many medical men in London will learn of the death on April 14th, at Montreux, of Dr. Cumston, who, though not the holder of any British qualification, was nevertheless a Fellow of the Royal Society of Medicine and a staunch admirer of the Royal College of Physicians of London.

Cumston, who was born at Boston, Massachusetts, in 1868, completed his early education at Vevey, and becoming ardently attached to Switzerland, pursued his medical studies at Geneva, graduating there as doctor of medicine in 1893 on the presentation of a thesis on subjects investigated in the laboratory of Prof. d'Espine, and marrying a Genevese lady who survives him and for whom—his inseparable companion during many years—great sympathy will be felt. After graduation, Cumston returned with his wife to Boston and soon won for himself a definite position as surgeon, chiefly interested in genito-urinary and allied subjects, and attached to several hospitals of importance. After 20 years or more of professional success in Boston, Cumston came back to Geneva, a year or two before the Great War, and though not entirely abandoning clinical interests, gave himself with increasing ardour to the study of the history of medicine, becoming privat-docent in the Faculty of Medicine and delivering yearly a course of lectures in his favourite subject. Here he accumulated a most excellent library concerning the history of medicine, and a really fine and beautiful collection of portraits—for the most part engravings and etchings of the historical heroes of medicine. He took a lively interest in the medical life of Geneva, participating in its social side and developing the activities of the Medical Society of that city, founding, in pious memory of two of his revered masters, the Julliard-Revilliod lectures, given annually by some foreign member of the medical profession. Here, too, in 1925, he had the great pleasure of presiding, in his own genial and kindly way, at the Fifth Congress of the International Society of the History of Medicine.

Latterly his health had somewhat failed, but several years ago he embraced eagerly the suggestion made to him by a friend that he should write in English a History of Medicine, and it was at once arranged that the volume should be included in the series known, under the editorship of Mr. Ogden, as the History of Civilisation. The book appeared in 1926, and has already achieved marked popularity and general success. By it Cumston's name will undoubtedly be remembered, and it is characteristic of the man. There have been and are many historians of medicine with greater technical equipment; there are others who are greater scholars, or who have made greater contributions to special departments of historical knowledge. But Cumston's book is a wide and generous survey of the subject, made by a man who had practised long and successfully as physician and as surgeon, and from whom nothing human was remote or alien. In fact, just as it may be said that one of his most successful "occasional papers" was a little essay, written in French, concerning "notre sympathique confrère François Rabelais," so was there much of Rabelais in Cumston.

Not that he was Rabelaisian in the sense in which the Englishman in the street understands the term, but that, like Rabelais a Hippocratic physician by nature and by training and, like him too, not without experience in a specialty that reveals a great deal of what is weakest and sometimes much of what is strongest in human nature, and with a wide knowledge of men and things, he became a great and kind-hearted observer and critic of life; impulsive and prejudiced, tolerant and wise, philosophical and genial, caustic and forgiving, and above all sympathetic to everything but what is mean and despicable. And it is perhaps not altogether fanciful to trace some resemblance between two portraits now before the writer—one, a copy of the famous Geneva likeness of Rabelais, the other, a recent crayon drawing by a Genevese artist of "notre sympathique confrère" Charles Greene Cumston.

F. G. C.

UNIVERSITY OF LONDON: *Prizes and Grants.*—A Carpenter Medal, together with a money prize, of the value of £20 in all, will be awarded by the Senate in 1928 for a thesis of exceptional distinction in statistical, genetic, comparative or experimental psychology, including the functions of the central nervous system and special senses, for which a doctor's degree (other than the Ph.D. degree) has been awarded during the period of three years ending on May 31st, 1928; applications before June 9th, 1928. The Senate will proceed shortly to consider applications, to be made before May 15th, 1928, for grants from the Dixon Fund, which are allocated annually for the purpose of assisting scientific investigations. Applications for grants from the Thomas Smythe Hughes Medical Research Fund, which are allocated annually for the purpose of assisting original medical research, should be sent in before June 15th. Further particulars of these prizes and grants may be obtained from the Academic Registrar.

The Laura de Saliceto Studentship for the Advancement of Cancer Research (value £150 a year), is a part-time appointment and may be held in conjunction with an appointment in a physiological or pathological laboratory or with a clinical appointment affording special opportunities for the study of cancer. It will be awarded for not less than two years and may be extended to a total period of five years. A candidate for the studentship may be of either sex and need not be a member of the University. He must submit to the Academic Registrar, not later than July 2nd, 1928, a statement of his qualifications, and give two referees.

Medical Graduates Society.—Sir Berkeley Moynihan will preside at the first annual dinner and meeting of members of the society, to be held at the Langham Hotel, Portland place, London, W., at 7.30 P.M., on May 8th. Any medical graduate of the University of London can join the society by sending a life subscription of £1 to the hon. treasurer, Mr. W. McAdam Eccles, 124, Harley-street, London, W.1.

ROAD ACCIDENTS IN 1927.—A return which has just been issued by the Home Office shows that in Great Britain last year 5329 persons were killed in street accidents caused by vehicles, against 4886 in 1926. The injured numbered 148,575, against 133,888. Motor-cycles were the most productive of accidents. They caused 1380 deaths and were responsible for injuries to more than 41,000 people. The highest accident risk is in London and the Home Counties. In London itself, last year one person in 1 was injured in a road accident, against one in 193 in Liverpool, one in 212 in Birmingham, and one in 244 in Manchester. In the Home Counties the proportions were: Essex, one in 172; Surrey, one in 217; Kent, one in 242; Herts, one in 248. At the same time the National Safety First Association points out that, in relation to the number of motor vehicles, the increase is the lowest since the war.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Edinburgh Corporation Bill.

In the House of Commons on Thursday, April 19th, the motion for the second reading of the Edinburgh rporation Bill,

Mr. Pethick-Lawrence moved the rejection of the Bill. ıough it came before the House as a private Bill this easure, he said, raised public issues of fundamental tional importance. They were all agreed as regarded e grave injury that was brought by venereal diseases the health and life of the community and as to the vital cessity for taking steps to eradicate them by every possible ans. The opponents of this measure, however, differed m the promoters as to the method to be adopted. The omoters believed that compulsion was the best means achieve the end which they all desired; the opponents, the other hand, believed that compulsion would have cisely opposite results to those which the promoters ıtemplated. Grave as was the infringement of individual erty involved by this Bill, he would be willing to tolerate f he really thought that the enactment of such a measure uld get rid more speedily of this disease throughout country. He was convinced, however, both by experi- e and a common-sense view of human nature, that the ct reverse would be the case.

A Hybrid Bill.

The Bill as put before the House was of a somewhat brid character. Concurrently with the text, the promoters l circulated a memorandum in which they proposed tuitously to make very considerable amendments. He s rather suspicious of these modifications so gratuitously red. But in whatever form the Bill was presented he nd it objectionable. The promoters said that it was essary to provide compulsion in order to catch defaulters. y had large numbers of people coming voluntarily for atment, but they found that before the treatment had n fully developed and a cure completely effected a tain number defaulted, and it was contended that if y they could introduce the principle of compulsion they ld oblige those who came for treatment to continue until cure was complete. The mistake in regard to that view s that they could not isolate the question of default; y could not graft compulsion on to the voluntary system. ital issue which the House had to realise was the extent which compulsion would cut off the supply of patients. uld anyone with any knowledge of human nature doubt t if this Bill became law volunteers would be considerably uced in number? Those who came forward would know t they would have to submit to the treatment whether y liked it or not. Perhaps they would have to submit hey went to a clinic to such a doctor as was prescribed them and they would have to continue the treatment il what was called a cure was effected. He appealed he medical men in the House to say whether any two lical men would agree exactly as to when a cure was cted. If that were so, from the patient's point of view, treatment might be continued almost indefinitely. consequence large numbers of patients would hesitate to e forward. Further, they all knew that in every form reatment there was a certain element of risk and danger, it might well be that certain unfortunate events would ur in certain cases. If that should get about the osition to coming for treatment would be very much ter still. But there was another vital question—ely, at what stage would the patients offer themselves reatment. At the present time patients in many cases e in the very early stages of the disease. Of 19,000 nteers over 4000, or something like 22 per cent., were d not to be subject to the disease at all. If, as a result is Bill, people postponed coming forward for treatment, might do so until some of the most important oppor- ties for dealing with the disease had gone. Moreover, ng the interval, they were very likely to consult quacks use they would hope in that way to escape the full rs of the complete treatment. Was it contended that e who were compelled to undergo treatment would e up in numbers for the falling-off of those who came ntarily? They would not belong to the well-to-do es, because the well-to-do would consult their own ate medical practitioner, and as there was no compulsory ication under the Bill, their cases would not be notified. as only the poor who were going to be dealt with. They going to be informed against by the Medical Officer of th or by a medical practitioner. But where was the cal practitioner going to get his original information? it suggested that he was going to get if from anyone chose to come and believe that he or she had been ted by the person in question? That, surely, was too preposterous to be believed. Or was the medical practitioner going to get it elsewhere from his own personal observation in hospital or clinic? If he was going to get it in the second way, was it not patent that that would have a very deleterious effect on men and women coming voluntarily to be treated in hospitals or clinics? Some of the most valuable work being done in the country, such as the attendance of mothers at prenatal clinics, would be gravely injured in consequence. But he thought it was very likely that public opinion would be too strong to allow this miscellaneous dragging into the net of all sorts of men and women in this way and in the end these provisions would probably be confined to prostitutes. If that were so, it would re-open the chapter of failure which many of them thought was closed for good.

The Percentage of Defaulters.

The Edinburgh Corporation, in a statement they had issued, had shown that in the five years from 1922 to 1926 the defaulters fell from 44 per cent. to 29 per cent. of those who were under treatment. This figure included those who were dead and those, such as seamen, who could not possibly go on with the treatment; so that the actual number of defaulters was very much smaller than the figures shown. In New South Wales, where compulsory treatment had been in existence for some time, they had succeeded in bringing back only 25 per cent. of those who defaulted. Were they going to try this dangerous experiment for the sake of a percentage such as that? They were recommended to pass this Bill on the ground that it would remain in force for under five years, and that then the question could be reconsidered. Was it suggested that there would be any reliable statistics to help the House to come to a conclusion then? They had definite medical opinion in Australia, where the compulsory system had been in force in certain States. He found that a medical conference on venereal disease held in Melbourne in 1922 passed the following resolution:—

> "That in the opinion of this conference there is no evidence to show that the passing of this legislation [i.e. the compulsory V.D. measures] has resulted in any reduction of congenital venereal infections. Judging from the infantile mortality rates under one month, there has hitherto been no such reduction."

He was strengthened in his opposition to the Bill by the knowledge that the Association for Moral and Social Hygiene was diametrically opposed to the measure and believed it to be a thoroughly retrograde step. It was also opposed by all the women's societies in the country, with a few small exceptions.

The Views of Two Great Teachers.

Dr. Little said he proposed to base his arguments for the rejection of the Bill entirely on medical reasons. He might claim some special right to speak in that sense, because for 26 years he had been at the head of two hospital departments in London where the treatment of these diseases was part of the work of the clinic which he conducted. He had seen very great changes in that long period. He went back to two great names in the history of syphilis, Hutchinson and Fournier, under both of whom he sat as a pupil. Hutchinson taught that two years was quite a sufficient treatment to guarantee a cure. Fournier, at the same time, taught that eight years was not more than an adequate period for the continuation of treatment. Those were rather irreconcilable views. Fournier had been proved to be far more right than Hutchinson and more prolonged treatment was the rule for both these disease than when he (Dr. Little) began to practise. The treatment of syphilis especially had been very materially altered by the introduction of two great inventions—a test for syphilis and a certain kind of treatment. Too much force had been attached to both these inventions, but there was common ground, even among medical men who differed so greatly, that early treatment was of essential importance in both diseases for two reasons: infectivity was earlier checked and the prospect of ultimate cure was very greatly increased in proportion to the earliness of the treatment. It was therefore far more important to get a new case than to go on treating an old case, and the Edinburgh Corporation seemed to him to have entirely missed the significance of the treatment of syphilis in the importance they attached to the question of defaulters. The number of defaulters was really a matter of a personal equation. The tests applied varied in different clinics and it was almost impossible to compare figures. The Trevethin Committee, which reported in 1923, made a tentative suggestion that special measures might be necessary to deal with defaulters, but they also said that the question of defaulters was not so serious a menace to public health as the statistics would imply. Not only was the number of defaulters decreasing, but the whole incidence of both diseases was rapidly diminishing in this country. He had that upon the authority of clinics in the City of London. The voluntary method was only instituted in 1916, and the period since then was hardly sufficient to declare that the system had failed, even

if it had failed, but in his view the system had been eminently successful. Medical opinion was overwhelmingly against compulsory methods. The Royal Commission of 1916 was much the most authoritative expression of opinion on these matters. The experts called by that Commission were the very flower of the profession in this country. Their opinion was overwhelmingly in favour of voluntary, secret, confidential services and upon that recommendation the clinics were established with an express promise to patients that secrecy would be observed. Upon that system the whole of the very great success of the clinics had been based. The British Medical Association, in 1923, issued a special circular to all its members—something like 30,000. The response to that circular was overwhelmingly against compulsory notification of venereal diseases. But that was a much less serious infringement of liberty than compulsory treatment, so that the greater carried the less. The Trevethin Committee consisted largely of eminent doctors. They were not men who knew syphilis or gonorrhœa from personal medical experience, and therefore were not a very happy committee, but as far as their authority went they supported the view that compulsory measures were not likely to achieve the purpose which was to secure early treatment.

Opposition to Compulsion.

The Edinburgh Corporation opposed this expression of medical opinion by a statement that the Edinburgh Division of the British Medical Association at a meeting held in Edinburgh, voted in favour of this Bill. He had taken the trouble to find out how many persons attended the meeting. He was told that the number who attended was something like 60. There were 1500 persons practising medicine in Edinburgh, and therefore 60 persons could not be said to voice the opinion of the medical profession in that city. The Bill would be absolutely unworkable without attention being given to the prospects of coöperation by the medical profession. The vast majority of the profession were opposed, and must be opposed, to compulsion because one of their most important traditions was the sacredness of the professional secret and if that tradition was threatened the medical man at once refused to have anything to do with the proposal. It was suggested by the Medical Officer of Health of Edinburgh, who was the protagonist of the Bill in that city, that they were not relying upon the doctors, and that they were going to obtain their information from a crowd of "competent officials attached to public health departments." They would be asked, he presumed, to go foraging about inquiring into the venereal history of the neighbourhood. He (Dr. Little) would not like to be one of those officials visiting a quarter like the East End of London where he had been a medical officer for some years. This was not a medical agitation, but a bureaucratic agitation. He would give the House some medical reason why the Bill would be unworkable. Compulsory treatment of diseases was an entirely new principle with them. As to the argument that specific fevers were subject to compulsory notification, he would point out that those fevers ran a very definite, well-established, perfectly circumscribed course which inevitably ceased at a given time which was well recognised. But the same did not apply to syphilis and gonorrhœa and no comparison was possible.

Standard of Non-infectivity.

The infectivity of syphilis and gonorrhœa was subject to no standard. The Trevethin Report emphasised that, and he would quote a passage which was in itself a sufficient argument against the Bill. The Report said :—

"There is another grave difficulty in the way of any form of notification reinforced by measures to compel treatment that in the present state of knowledge there is no standard of non-infectivity or cure generally accepted by the medical profession, and until this has been attained it is difficult to see how any system involving notification and compulsory measures of treatment could be applied."

That was absolutely true of the scientific position of this question at the present moment. There was no agreement on this question in the medical profession. Reliance to be placed both upon the new test and the new treatment had been greatly over-estimated by lay opinion. They started with the idea that they had a perfectly easy scientific test and that they had a method of treatment which would eliminate syphilis. Ehrlich himself announced that his drug was going to sterilise the patient by one dose. Both these theories had gone by the board absolutely. It was a very difficult test to apply. It was a physiological test, not a chemical test, and certain laboratories had become famous for their skill, or otherwise, in performing the test. It was proposed by the Bill that detention and treatment should be compulsory until the patient could obtain a certificate of cure from "any medical officer." Detention had been ostensibly abandoned by the Corporation by the relinquishment of Clause 3, but he was told by one of the protagonists for the Corporation that they did not attach very much importance to the relinquishment of that clause, because they thought that they could get all they wante by the application of Section 7 of the Public Health Ac by which any infectious disease could be detained un infectivity was over. So that detention was still conter plated by the terms of the Bill, and detention for perio which varied enormously and rested on the certificate of medical practitioner. He was not behind any man in t House in respect and love for his profession, but he recognis its limitations, and he thought it was impossible at prese to expect that the general profession throughout the count would be in a position to give certificates of that kind th would be of any value at all. The tests and the treatme for this disease required very wide and specialised experien and team-work by many experts. A case presenting itse at a hospital was not treated by one man ; it was referr to half a dozen people who went into the case very careful before making any report. Was that possible anywhe in general practice ? They were also asked to rely up the treatment given by any medical practitioner. Aga he said that the modern highly specialised treatment w very dangerous except in highly skilled hands. He h had three deaths from "606" in his personal practic They were going to compel persons by law to submit treatment which carried such risks. It was an impossib proposition in the present state of medical science. Certi cates given under these conditions would be largely valuele The patient would be assured that he was cured when was not cured. The practitioner would have a very stro motive for giving a certificate ; common humanity wou urge him to give a certificate when he could, in order enable the patient to avoid the horrible consequences this Bill in regard to detention and treatment. A default had no illusions at all ; he knew he was not cured, but t patient who was told he was cured was a source of gre danger not only to himself, but to the public. The seco alternative was that the patient should be kept unc treatment for much longer than was necessary. Th again, was a very severe handicap to the citizen wh unfortunately, was caught in this hideous machine. It w suggested that the experiment could be restricted Edinburgh and limited to five years. The experiment cou not be restricted to Edinburgh, because it could not effectively compulsory if it was so restricted. Nothi would be easier for a patient than to get out of the co pulsory area and go to another part of the country wh the more sensible voluntary system was still in force. could not be restricted in point of time, because the eff of introducing the compulsory system would be at on to annihilate the whole voluntary system. After five ye of compulsion what patient would think that he could to Edinburgh and again have confidential treatmen There was no reason for panic legislation. Let them go with the present highly successful system and endeavc to improve the methods of its administration.

A Bill to Stamp Out Disease.

Sir PATRICK FORD said that Dr. Little admitted that th was a considerable conflict of medical opinion. He (Sir Ford) would suggest that, in Edinburgh, which had one the finest medical schools, and where they had the lat methods and the latest information, they ought not to guided by the more antiquated ways of looking at th things. Where there was a conflict of technical opini as in this case, the floor of the House of Commons was n a place suitable for clearing up such matters. The obj of this Bill had nothing to do with moral or social proble It was to stamp out disease, and some form of compuls was sought to deal with what he might call the dead-e of cases which for some years had remained steadily between 900 and 1000. It was admitted that the Edinbu clinic had been run with the greatest skill and success, they could not get away from those 900 to 1000 centres f infection every year which were dangers to the neighbourhc and to the country. There was no suggestion by the p motors that voluntary work should cease, but they contenc that in a certain type of case, which might perhaps recklessly vicious and was entirely recalcitrant, more pov was needed. He did not think the Bill interfered w personal liberty any more than any of the regulations un the Public Health Act. All the promotors said was that wh it had been established that there were these danger cases of venereal disease they should be entitled to segreg them, and if the common sense of the patients did not te them to submit to treatment, they should remain segrega so that they could not infect other people. The medi officer was not entitled to act on any information exc from a doctor unless he took reasonable steps to make su He did not believe that this was going to open the doo blackmail. He did not believe that any responsible medi officer was going to do these things in a lighthearted manr If the information which was laid proved to be false, only was there a small fine provided for in the Bill, but n action for damages for a very considerable sum would The whole weight of the opinion of local authorities n

cotland was behind this Bill. The Convention of Burghs 1922 passed a resolution in favour of the compulsory tification of venereal disease, and at their most recent nference, held on Jan. 27th, 1928, in Edinburgh, they ssed the following resolution :—

"In the opinion of this conference the present law and achinery are inadequate to secure the proper control and eatment of venereal disease, and that it is essential that further wers should be conferred on local authorities in the direction compulsory measures to secure submission to treatment by all rsons infected by a venereal disease and continuance under eatment until discharged."

he Scottish Board of Health in 1922 said :—

"The Board are still of the opinion that the first step should be ot notification of cases of venereal disease but compulsion on rsons knowing or having reason to suspect that they are ffering from these diseases to submit themselves for treatment, id having so submitted themselves, to continue under treatment ntil discharged by the medical officer in charge of the treatment. he Board have under consideration a draft Bill dealing with is question, that might be promoted when opportunity offers, id in regard to which they propose to invite the observations of ie Convention of Royal Boroughs before any overt steps are ken."

he Scottish Board of Health did not produce the Bill id the Edinburgh Corporation and its medical officers ho had led the way in this matter felt that they could not ait any longer. He submitted that it was the duty of ie House to give a second reading to this Bill in order that might be sent to a Select Committee, where evidence uld be taken and the matter could be thrashed out in a dicial manner.

Salvarsan Treatment.

Dr. SALTER, in supporting the rejection of the Bill, said at any law was bad if it offered practically unlimited portunities for evasion and if it was unequal in its incidence the community. The treatment of syphilis was by an jection of highly toxic substances of the arsenobenzol oup, popularly known as "606"—salvarsan or one of e later derivatives. Speaking as a medical man, he lieved that that method of treatment was effective. If had the misfortune to become infected with one of these seases in the ordinary course of his professional work he ould be most eager to avail himself of that treatment, it he would do so with his eyes open, knowing that he was cepting a very grave risk, because death resulted from is treatment in a considerable number of cases every year this country. Every few weeks the medical press reported ses of grave accident following the treatment and a very rrible disease known as acute yellow atrophy of the liver llowed not infrequently. Other great damage to health well as sudden death following an injection were also ported from time to time, and he submitted that it was entirely new principle in British law that the public re to be compelled to take risks of that description. It s not a principle with which the medical profession, as a ole, had ever associated itself. Though he accepted the dern method as being efficient, there were many doctors high standing who did not regard it as any advance on e older method. It was true that a patient could apply another medical man to give him treatment, but in the e of the poorer people the patient had practically no tion. There was another very serious position which uld arise if this Bill became law. At present, if a patient luntarily attended a centre and happened to suffer injury was killed as a result of the treatment no liability rested on the doctor or upon the institution, clinic, hospital, authority supplying the treatment. The position, wever, would be quite different under this Bill. He sub-ted that the method proposed in the Bill was entirely necessary. The Corporation of Edinburgh had published ures in which they stated that the percentage of defaulters l been reduced from 44 to 29, but the Medical Committee the House of Commons had had the advantage of meeting umber of officials of the Corporation, and they supplied m with another series of figures. They were told that 1922 the percentage of defaulters of all cases who pre-ted themselves for treatment was 18; in 1923 15; 1924 12; in 1925 13, and in 1926 12. He was subsequently rmed that in 1927 the figure was 11. That would seem show that the present voluntary system was distinctly ective in spite of the fact that the Corporation had only official who acted as a follower-up of the defaulting es. He submitted that before introducing such drastic posals as those in this Bill, further methods on voluntary s with more effective medical persuasion and an increased nber of followers-up should be undertaken. If that were e there was every prospect that the number of recalci-nts with the exception of an extremely small minority uld be abolished altogether. The experiment of com-sion had been made in a great many countries, but herto not in Great Britain and Holland. It was inter-ng to note that the number of defaulters was smaller Great Britain and Holland than anywhere else. He was rmed that the chief director of the Polyclinic at Amsterdam had stated that with the following-up system 95 per cent. of syphilitic men and 85 per cent. of women had remained continuously under treatment during the two years the system had been in operation, and that these figures could not be surpassed by those published in any country where compulsory treatment had been in force. If Holland could achieve such success without compulsion, there seemed every reason to hope and believe that in this country, with improved methods, equal success would be attained. Many of the persons who had attended for treatment and then defaulted were in some cases infectious, but in many cases they were not infectious. When there was no proof that people were infectious or dangerous to others it was an extremely serious thing to say that they should be punished if they refused to continue treatment. The Bill did not contemplate any steps to prevent people who were infectious continuing to infect other people, but on the other hand, it proposed to deal with people who might not be infectious at all, but had simply not followed up their treatment for as long as the medical officer thought they should have done.

SIR BASIL PETO : Would the hon. Member support a Bill for segregating people who are suffering from venereal disease until they are certified cured ?

Dr. SALTER said he would not support such a Bill, because he believed that it would be ineffectual and would make the position worse. He believed that this Bill would increase the amount of venereal disease ; at any rate, there was a risk that it might do so, and there was no evidence that it was likely to diminish it. He hoped, therefore, that the House would reject the measure.

V.D. and the Infectious Diseases Acts.

Dr. DRUMMOND SHIELS said that he was rather surprised that a better case against the Bill had not so far been made out. The Bill was designed to fill a gap in the operation of the Infectious Diseases Acts under which they had had compulsory powers since 1889. The reasons why venereal disease had not been brought under these Acts were various. Up to comparatively recent times the seriousness of these diseases were not understood and their responsibility for disastrous after-effects was not realised. The specific causes were not known and there was no certainty of a cure. There was, however, high medical and legal authority for believing that they could come under the operation of those Acts, and certain parts of this Bill were identical with the provisions of those Acts. It was rather curious to find so many hon. Members demanding preferential treatment for those suffering from venereal diseases, while perfectly willing to continue to deny to the victims of other contagious diseases the liberty and freedom of which they were at present deprived, often at very great inconvenience to themselves. It was quite impossible for the Royal Commission to recommend compulsory methods in 1916, but they visualised a time when compulsory methods might be necessary. The Trevethin Committee also very definitely outlined something like the experiment which was proposed in this Bill. Nowadays compulsory methods in connexion with ordinary infectious diseases were carried out without any difficulty. There was only one serious and sensible argument against the Bill and that was that it would hamper voluntary treatment and drive the disease underground. The people who were most dogmatic on this question were either only theorists or people who had no personal association with the treatment of these diseases. They found that the venereal diseases officers, medical officers of health, and members of public health committees took another view.

Dr. SALTER : Certainly not.

Dr. SHIELS said he meant in Scotland.

Mr. BUCHANAN : Certainly not.

Dr. SHIELS said he was entitled to state his own opinion, and he had good evidence for what he had said. He believed that the voluntary system could go on perfectly well and be supplemented by the compulsory parts of this Bill. As to the terrible risk to the patient in connexion with treatment there had been only one death following injection in Edinburgh since 1917.

Dr. SALTER said that it had been stated in the medical press recently that over 30 deaths under these circumstances had occurred.

Dr. SHIELS said that he was speaking of experience in Scotland. The treatment had now become so safe that a public authority was perfectly justified in using the methods proposed in this Bill. After all, medical men knew that if there was potential danger in the treatment there was an absolute certainty of grave danger awaiting these people if they were not treated. Were they to go on indefinitely with a system which was very like pouring water into a sieve ? Last year Edinburgh spent over £20,000 on the treatment of this disease. The estimates of the Board of Health for the treatment of this disease in Scotland showed that £62,000 would be required next year. That was only two-thirds of the amount, because the local authorities had to make a contribution, which raised the total to over

£87,000, or £4,000 more than last year. This did not suggest that the purely voluntary system had been successful in Scotland. In the whole of Britain they were spending over £300,000 in dealing with this disease.

Preventive Medicine.

The ideal of the medical profession was preventive medicine and they were looking forward to a time when they would not be curing disease, but would be keeping people well. It was very depressing to a clinic doctor to find that much of his treatment was of little effect because of the carelessness and indifference of a certain section of the population. General hospitals, Poor Law hospitals, asylums, and prisons were very largely filled with the end products of this disease. They had, in many cases, a development of valvular disease of the heart, seriously incapacitating and painful to witness; they had arterial and nervous diseases often paralysing in their effects. Insanity and blindness might also follow the neglect of these conditions. The expert of the Ministry of Health on this subject at the recent Imperial Conference at Wembley estimated that the treatment of venereal disease at the present time saved £50,000 in asylum expenses, and if treatment could do that on only one aspect of the end-results of this disease, what would entire prevention achieve, even in economy? He believed that compulsion and early treatment of these residual cases would result in the prevention of many of these later developments, and that would release a large number of much-needed beds in the ordinary hospitals. His opinion was that if the Bill had any effect upon the voluntary attendance at centres it would be a good effect. At the present time one of the disadvantages in the treatment of venereal disease was that the public did not sufficiently realise the seriousness of it and there was no doubt that compulsory powers would awaken the public mind on the subject. With regard to treatment by quacks it was quite well known that since 1917 it had been illegal and a serious offence for any unqualified person to treat venereal disease. Therefore, this fear of interference with the voluntary system had no basis in fact or experience to support it, and there was at the worst so slight a danger as not to stand in the way of this important experiment being carried out, especially at the hands of those who had carried out the voluntary system so conscientiously and so successfully. He was surprised to find some women's societies against the Bill when this disease meant so very much to women. He would give a few cases to the House which justified the proposals of the Bill.

Here was a case of a male patient, single, treated for three weeks for syphilis and defaulted. Married one year later, infected his wife, who had two miscarriages and subsequently two children who survived, but were found to be infected with syphilis. In addition, other members of the same household, aged 12 and 14, were innocently infected with syphilis on the lips. Four years later this man had an abscess of the brain and paralysis due to syphilis. Power to compel this individual, in the first instance, to complete his treatment would have prevented the infection of his wife, the miscarriages, the inherited syphilis in his two surviving children, the acquired syphilis in two children in the same household, and his own death.

Here was another case: Female, aged 36, seen at hospital and delivered of a still-born child due to syphilis. Advised to attend for treatment and repeatedly implored to do so and bring her family. Two years later reported with child, aged 5, suffering from loss of sight due to syphilis. Mother at that time seven and a half months pregnant; child subsequently born suffered from syphilis. Mother now stated that she wished she had been compelled in the first instance to attend for treatment. The eldest child's sight would undoubtedly have been saved and both saved from suffering from syphilis.

Another case was that of a child, 6 days old, brought to hospital suffering from ophthalmia neonatorum, which led to blindness. Father and mother found to be infected. Both refused to continue treatment, although both told they had syphilis and gonorrhœa. Child died. Eighteen months later the same mother reported to hospital with another child, suffering from syphilis, which also died. Father and mother had consistently refused to be treated and were both of child-producing age. The second child could certainly have been saved if father and mother had been treated.

It seemed to him, also, that these women's societies might very seriously consider the case of the children. In the Edinburgh centre there were between 200 and 300 children attending. All types of people attended the clinics and people of all social grades. There had never been any class distinctions and there would not be in the future. Compulsory methods in Europe had only been against prostitutes and had no reference to the system suggested in this Bill. In Germany, however, which had always been a progressive country in public health, a few weeks ago a system was introduced on very similar lines to this Bill. In some towns in the Dominions, such as Toronto, there was a similar system at work. In Toronto less than 2 per cent. of prosecutions were required to make the system effective.

Effect of Compulsion in Australia.

He had looked into this question in all the States of Australia and had a special interview with the Director of Medical Services in Melbourne. They were perfectl satisfied with the system there and considered the com pulsory powers of great value. The Commissioner Health for Western Australia said:—

"V.D. clinics are well attended, and literally hundreds patients have been returned for treatment chiefly by persuasio who without the Act with its compulsory powers would hav remained partially treated and so sources of infection . . . Suc prosecutions as there have been have been almost entirel against men. Very few women have been brought up, and suc as have been have had plenty of warning and have been knowin and deliberate offenders . . . .

"I think it will be conceded by all fair-minded people that th Act is certainly doing good, and it is a well-known fact tha although there is a Vigilance Committee in this State, which ha asked anyone who considers himself or herself wronged by th administration of the Act to report themselves and their case will be inquired into, no such case has been brought forwar since the Act came into operation in 1916."

As regarded the criticism that these powers ought not t be sought in a local Act, he would point out that the Boar of Health in Scotland had more than once in its Repor spoken of the necessity for compulsory measures. Th English Ministry of Health, however, had always seeme to have a curious prejudice against any legislation on thi subject. It seemed strange that a united Scotland, wit all its local authorities behind this Bill, should be prevente by an English Ministry of Health from making an importan experiment in public health in connexion with this importan disease. He believed that those who opposed the Bill wer undertaking a very grave responsibility.

Progress Under the Voluntary System.

Sir JOHN GILMOUR, Secretary of State for Scotland, sai he regretted that he would have to advise the House, quit plainly and quite emphatically, to reject this Bill. He di so after very careful consideration of the question with h advisers. They would all agree that this disease was scourge which affected the health of the community and tha it was essential to make as great progress towards it elimination as possible, but in this problem, as in man others, the measure of progress must always be in proportio to, and not in advance of, the volume of public opinio which supported it. He and the Scottish Board of Healt recognised the skill with which the Edinburgh Corporatio and other authorities throughout Scotland had endeavoure to deal with this problem. But while they quite recognise the intense anxiety of those responsible to make rapi progress, that did not remove the difficult question as t whether, if they had compulsion, they would be able t deal with these cases any more readily than at the preser time. Under the voluntary system they had admittedl made great progress. He did not feel convinced, nor di his advisers, that the possibilities of education and voluntar teaching and, if they liked, the pressure of public opinio had been fully exhausted. In those circumstances the Hous should think very carefully indeed before making an exper ment which was admittedly one with very far-reachin consequences and one which was bound to have its effe on areas far beyond the city in which it was being mad It was an experiment which, if it failed or partially faile was bound to have reactions which many of them cou not foresee. He therefore asked the House to reject th measure.

Common Grounds.

Lieut.-Colonel FREMANTLE said the House had be afforded that evening one of those delightful opportuniti of seeing the medical profession divided. They we divided all the more because of their honesty and genuinene of determination to tackle evil questions. But there we certain definite grounds which they had in common. the first place they had a common realisation of the inten seriousness of the position which they were trying to mee The Royal Commission in 1916 came to the conclusion th no fewer than one person in ten of the whole populatio of the large cities was infected with syphilis, which was o of the great killing diseases. Gonorrhœa was equal prevalent, or more so, and that was one of the great crippli diseases. It was true that the number of defaulters ha been reduced and he hoped that it would continue to declin But leaving aside statistics, he asked any impartial man woman of the world whether they imagined that any syste of voluntary treatment was going to clean the slate, or secu the treatment, of those who were recalcitrant? Of cour it was not. The Government, from the pronounceme which they had just heard and those who were opposed the Bill, were quite content that nothing should be do for these people.

Several hon. Members: Certainly not.

Colonel FREMANTLE said that these people would refu voluntary treatment. They were careless and could n be got at by voluntary measures. The medical professi and all who had to deal with public health were unanimo that the main basis of the treatment of the disease an still more, the measures of prevention must be on a volunta

ystem. There was no question of trying to get over that. They intended to keep the voluntary system under this Bill, but the question was, could they clear up the dregs and the recalcitrants at the bottom? It was because he believed that the Edinburgh Corporation had met with very great success in this treatment that he supported this Bill as an experiment. He happened to be the only member of the Trevethin Committee in the House. Anybody who had been through this problem as that Committee went through it would realise how intensely serious was the proportion of recalcitrants and defaulters. Nobody could say that a Corporation such as that of Edinburgh, who were fully conversant with the difficulties and dangers and were a responsible elected body, were not the ideal body to make one of those experiments on which alone they could build up a system of general administration.

After further debate the motion for the rejection of the Bill was carried by 156 votes to 93.

Bethlem Hospital Bill.

The Bethlem Hospital Bill was read a second time in the House of Lords on Thursday, April 19th.

The Budget Statement.

Mr. CHURCHILL (the Chancellor of the Exchequer) made his Budget statement in the House of Commons on Tuesday, April 24th. He announced that it was proposed to introduce a new form of National accounts on the basis of which the expenditure for 1928 was estimated at £727,381,000. The revenue, including £13,200,000 from the Currency Note Reserve, was estimated at £761,083,000, leaving a gross total prospective surplus of £33,702,000. There would be in addition to the Sinking Fund, including £13,200,000 from the Currency Note Account in order to bring the fund again to £65,000,000. This would absorb £14,000,000. A reduction of ½*d.* per lb. on the sugar duty would cost £2,300,000. Further relief would be given to income-tax payers in respect of children's allowances. The allowance for the first child would be increased from £36 to £60, and for other children from £27 to £50. The relief would also be made applicable in the year of the infant's birth. This would affect 650,000 households. The man with £400 a year with three children would be freed altogether from tax; the man with £500 a year in the same position would have his income-tax halved and receive a relief equal to 8*s.* 9*d.* reduction in standard rate; the £600 a year family would receive a relief equal to 1*s.* 6*d.* reduction in the standard rate; the £700 a year family the equivalent of 1*s.* 5*d.* reduction in standard rate; the £800 a year family the equivalent of 1*s.* 2*d.* reduction in standard rate; and the £1000 a year family more than 8*d.* reduction in standard rate. The cost of this concession would be £2,100,000 in the present year, and £4,500,000 in a full year. It was proposed to impose a duty of 4*d.* a gallon as from April 25th on the lighter hydrocarbon oils imported or derived from imported materials. The formula would cover not only petrol and other forms of motor spirit, but also kerosene and white spirit. It excluded the heavy oils known as fuel oil, Diesel oil and gas oil, and also lubricating oils. It would cover one vegetable oil—namely, turpentine. Stocks under 10,000 gallons at present in the hands of garages and private individuals would escape duty. In view of the oil duty some mitigating reductions in licence duties on heavy and hackney vehicles would be made. The Chancellor of the Exchequer outlined a new scheme for relieving rates on productive industry and announced that in connexion with that scheme two new Bills would be introduced. The Valuation (Ascertainment) Bill would be introduced by the Minister of Health as soon as possible to define the scope and direction in which the relief should be given. In November the Minister of Health would introduce the main Local Government Bill dealing with the reimbursement of local authorities and creating larger areas. The opportunity would be taken to establish a system of block grants subject to quinquennial revision. He hoped that the Local Government Bill would receive the Royal Assent by Christmas, or at any rate by Easter. On this basis, and provided new valuations were completed by about the same date, the first relief to rates on productive industry would begin with the rate payment of October, 1929. The money to pay for the new system of rate relief would be provided out of the new oil taxation provided in the present Budget.

HOUSE OF COMMONS.

Wednesday, April 18th.

Treatment of Venereal Disease at Sea.

Mr. BUCHANAN asked the President of the Board of Trade if he was aware that it was common for cargo ships to go to sea without any medicines or drugs for the treatment of venereal disease; and if he proposed, by either voluntary or compulsory method, to see that each ship was supplied with such remedies.—Mr. HERBERT G. WILLIAMS (Parliamentary Secretary to the Board of Trade) replied: The hon. Member has been misinformed. All cargo ships trading to ports abroad are required to carry medicines, including those necessary for the treatment of venereal disease, and ships are inspected from time to time to see that this requirement is carried out.

Cost of Health Insurance Drugs and Appliances.

Sir ROBERT THOMAS asked the Minister of Health what was the average cost of drugs and appliances per insured person during 1927 in the areas of Welsh insurance committees and in the areas of English insurance committees, respectively.—Sir KINGSLEY WOOD replied: The figures for 1927 were approximately 29·5 pence in Wales and 35·1 pence in England.

Thursday, April 19th.

Health of Asbestos Workers.

Mr. BRIANT asked the Home Secretary if his attention had been called to the dangers to asbestos workers from asbestos dust; if he would have a periodical examination of the workers; and if inquiry was being made as to the dangers attending this industry.—Sir WILLIAM JOYNSON-HICKS replied: Two cases of suspected danger to health have been recently reported to the Factory Department and the matter is being carefully investigated by the medical inspectors. Should their inquiries show that any special precautions are required, the necessary steps for the purpose will be taken.

Animals and Poison-gas Experiments.

Sir ROBERT GOWER asked the Home Secretary the number of dogs and other living animals, respectively, which were during the years 1926 and 1927 subjected to poison-gas experiments at the War Department experimental station, Porton, Wiltshire, or elsewhere in the United Kingdom under 39 and 40 Vict., cap. 77; and under what certificates and by what licences were such experiments performed.—Mr. DUFF-COOPER, Financial Secretary to the War Office, replied: No dogs were used for these experiments at Porton or elsewhere. Information regarding experiments on other animals at Porton is given in the following table:—

—	1926.	1927.	Total.
Rabbits	385	86	471
Goats	3	2	5
Guinea-pigs ..	193	259	452
Cats	20	11	31
Monkeys	—	1	1
Mice	31	26	57
Horses	12	—	12

The above experiments were carried out under licence alone or under Certificates A.1. and F.1.

Experiments at the Physiological Laboratory, Cambridge.—1926, 214 under Certificates A.1 and E.1; 1927, 28 under Certificate A.1.

Maternity and Child Welfare Centres.

Mr. JOHN PALIN asked the Minister of Health the number of maternity and child welfare centres in existence in England and Wales at the present time, and the figures at this time last year.—Mr. CHAMBERLAIN replied: The total number of these centres known to my Department was 2685 at the beginning of the present month, as compared with 2575 at this time last year.

Clinics for Treatment of Rheumatism.

Mr. HARDIE asked the Minister of Health whether it was the intention of the Government immediately to increase the number of clinics for the treatment of rheumatism.—Mr. CHAMBERLAIN replied: I shall watch with interest the results of experiments which are being made in the provision of treatment in clinics for persons suffering from rheumatism, but it is not the intention of the Government itself to set up such clinics.

Official Criticism of Panel Doctor's Prescriptions.

Sir COOPER RAWSON asked the Minister of Health whether his attention had been called to the Report of the East Sussex insurance committee with regard to a case in Hove, where it was alleged that the panel doctor was visited by a regional medical officer of the Ministry, who criticised his methods of prescribing, and that subsequently the doctor was threatened with action on the part of the Ministry unless he prescribed medicines of a cheaper character; and what was the reason for such an interference with the jurisdiction and authority of the panel committee.—Mr. CHAMBERLAIN replied: My attention has been called to this case and I am carefully considering the report to which my hon. friend refers. I must point out, however, that the visit of the regional officer was in fact directed to ascertaining, in accordance with the Medical Benefit Regulations, whether the case was one which should be referred

to the Panel Committee and that the warning issued to the doctor indicated that in certain circumstances such a reference might have to be made.

Lost Cards and Eligibility for Sickness Benefit.

Colonel VAUGHAN-MORGAN asked the Minister of Health whether, in the case of regular contributors under the National Health Insurance Act inadvertently losing their cards on which the stamps had been duly fixed and cancelled, he would take steps to see that these people should be credited with the amount of their paid contribution and entitled to sickness benefit under the scheme instead of having to defray the cost of stamps for a duplicate card or being treated as a person in arrear with contributions and therefore not eligible for sickness benefit.—Mr. CHAMBERLAIN replied: Under the statutory regulations governing the benefits of insured persons in arrears a contributor cannot receive credit for contributions paid until a duly stamped card is surrendered to his approved society. I regret that it has not been found practicable to allow an exception to be made in the case of contributors who claim to have lost their cards, as it is essential for the proper working of the health insurance scheme that nothing should be done which might conduce to laxity on the part of insured persons with regard to the care and surrender of their cards.

Sanitary Conditions in the Hop-fields.

Mr. BRIANT asked the Minister of Health if his attention had been called to a statement by the medical officer of health for Kent that the by-laws affecting the conditions of hop-pickers had not been adopted in their entirety and also attributing negligence in their enforcement by the local authorities; and, whether in view of the danger to the health of the hop-pickers and also the neighbourhoods in which they temporarily reside, he would see that the by-laws were uniformly adopted and enforced.

Dr. VERNON DAVIES asked the Minister of Health if his attention had been drawn to a recent address by the county medical officer of health for Kent referring to the sanitary conditions of some hop-picking camps, and the administration of certain rural district councils in connexion therewith; and what proceedings, if any, he proposed to take to remedy the conditions referred to?—Mr. CHAMBERLAIN replied: Yes, Sir. This address and a report made by the Medical Officer of Health are receiving my consideration. I have no power to compel a local authority either to adopt or to enforce by-laws on this subject, but I have represented to the local authorities the importance of their administrative functions in this matter and, if necessary, I shall continue to do so.

Massage and Electro-therapeutic Treatment.

Captain FRASER asked the Minister of Health, if, in view of the value of massage and electro-therapeutic treatments in hastening the return to physical fitness of persons who suffered from accident or disease, causing loss of time or efficiency in industry, he would consider making these treatments an additional benefit in national health insurance.—Mr. CHAMBERLAIN replied: Under the National Health Insurance Bill now before the House, provision is made for the inclusion in the list of additional benefits of a new benefit under which approved societies will be able to make payments towards the cost of massage and electro-therapeutic treatment of their members in approved institutions.

Captain FRASER: May I ask whether the answer means that massage will be a direct additional benefit or will it be given indirectly through institutions.—Mr. CHAMBERLAIN: It takes the form of a new benefit. Power is given to make contributions towards the cost of massage.

MONDAY, APRIL 23RD.

Sanitary Conditions in the Hop-fields.

Mr. BRIANT asked the Minister of Health if he would consider the introduction of a Bill for the compulsory registration of hop-pickers' camps so that adequate provision for the health and comfort of the workers might be assured before such camps were opened, and (2) if the reports of the inspectors of his department who visited the hop fields during the last season confirmed the statements of the medical officer of health for Kent as to the conditions in the hop-pickers' camps; and if the reports will be available to the public or Members of the House.—Sir KINGSLEY WOOD replied: Though there has been an improvement in recent years, I cannot say that my right hon. friend is satisfied with the conditions existing in the hop fields. The reports of officers of my department are confidential documents and there appears no sufficient reason for their publication in this case. The whole question is receiving my right hon. friend's further consideration, but I may observe that compulsory registration of camps would not necessarily provide any solution of the difficulties.

TUESDAY, APRIL 24TH.

Small-pox in London.

Mr. LANSBURY asked the Minister of Health the to number of cases of small-pox notified in London duri the past 12 months ended March 31st, the number of ca which had been traced to homeless persons, and the numb for which no contacts had been traced; and the to number of small-pox cases notified for the whole count during the same period, the number of those vaccinat and the number of deaths certified as due to small-p for the same period.—Sir KINGSLEY WOOD replied: T answer to the first part of the question is 51. There w seven cases of small-pox during this period amongst homel persons in London, but information is not available as the number of persons who had been in contact with th cases and who subsequently either developed small-pox escaped infection. 13,348 cases were notified in Engla and Wales during the period in question. Complete p ticulars as to the vaccinal condition of these cases are n available. During the same period small-pox was ente on the medical certificate as the cause, or one of the caus of death in 66 instances. The figures quoted above are, course, provisional.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURG ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROY FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW At recent examinations the following candidates w successful:—

THIRD EXAMINATION FOR CONJOINT DIPLOMA.

Robert Leitch Allan, Mohammed Umar Hayat, Frank Rob Bernard Howard Kennedy, Walter Phillips Kenne John M'Connell, Harry Michaelson, John Ernest Morris William Oscar Molander, James Ian Meikle, Helen Hallic Norris, John M'Kichan Reid, William Charles Ross, a Mary Thomson Wilson.

Pathology.—Cyril Bellamy and Joseph Everett La Frenais

Materia Medica.—Andrew Brock, Kenneth Wilkinson Bru John Cochran, Albert Benjamin Foo, Arthur Royle Hunt, Donald Forbes Johnstone, William Evan Macdoug Mahamarakkalage Anslem Perera, Elsie Janet Duff Sc Robert John Giffen Sinclair, and Lawrence M'La Young.

FINAL EXAMINATION FOR CONJOINT DIPLOMA.

Thomas Gilchrist, Henry Thomas Chapman, Agnes Donalds Anthony Francis Joseph Casie Chitty, James Tay Erskine, John Edward Mulholland, Radcliffe Dougan Jor Sri Kishan Kapur, Norbert Anthony Felix de Soy Herbert Arthur Shakerley, Julius Leibman, Willi Wallace, Mohamed Rahman Ramjohn, Surindro N Chopra, John Pullar Logan, John Lees, Lewis Meredy Davies, Eileen M'Cabe, Norman Macleod, William All Andreas Johannes de Villiers, Arthur Barton Pilg Amies, Robert Dalziel Buckner, Ahmad El-Saved Ammar, Cecil Benjamin Goodwin, Tarabai Kelarl Hyman Louis Cohen, Clarence Edward Vaz, and Bish Singh.

Medicine.—Nutting Stuart Fraser, Aaron Jacorovit Norman Webster Laing, Horace Walpole Alexan Marshall, Hubert Melizan Clement de Silva, and Ferdin Ernest Llewellyn Stewart.

Surgery.—Walntantrigi Daniel Alvis, John Campbell, Hut Gunavatana, Harry Lazarus, Mahmud Riffaat, Chadr Krishna Row, Barney Schulman, and Oscher Stern.

Midwifery.—Okunade Ajibade, Aquilino Joseph Fra Almeida, Walntantrigi Daniel Alvis, Alexander Ho Frew Arnott, John Campbell, Alan Mackenzie Fra Hubert Gunavatana, Aaron Jacorovitch, Kandiah Ka gasabapathy, Norman Webster Laing, Harry Laza Mary Elizabeth Josephine Magee, Augustine Byrne O'Br Barney Schulman, Ferdinand Ernest Llewellyn Stew Chadrian Krishna Row, and Hope Lazarus.

Medical Jurisprudence and Public Health.—Ronald Dun Allison, Ivor Campbell, Hugh Craig, Donald Peter D Theodore Herzel Fairley, Frank John Fell, Percival Art Pitt Fennell, Jate Ranjan Sen Gupta, David Alexan Herd, Mahabalage Don Daniel Jayawardana, John Kear Nashed Younan Labib Christopher Leo Xavier Sathien Muttukumaru, Thiam Hock Oh, James Baird Reid, C Hartley Rowe, William Paterson Shand, Raym Ponsonby Carew-Smyth, Ian William Spence, and Em Cadwaladr Thomas.

UNIVERSITY OF ABERDEEN.—Lord Meston has be nominated for election as Chancellor of the University in place of the late Duke of Richmond and Gordon.

GRENFELL MEDICAL MISSION.—Sir Wilfr Grenfell, F.R.C.S., has arranged to visit England fr Sept. 25th to the middle of December. He will give lectu on his medical work in Labrador during the past 35 ye

UNIVERSITY OF GLASGOW.—On April 21st the llowing degrees were conferred :—

M.D.

*Muriel J. Brown, *W. C. Harvey, *W. A. Horne, †W. Brown, †J. W. Graham, †W. Napier, and D. O. Taylor.

CH.M.

D. R. E. Roberts.

M.B., CH.B.

With Honours.—J. S. M. Robertson.
With Commendation.—D. Fraser, D. R. Milligan, R. H. Moyes, Constance D. Roberts.
Ordinary Degree.—J. Aitchison, T. R. Baird, T. Barrowman, C. Black, R. Brown, D. H. W. Cameron, J. M. Carnovcki, W. Craig, Mabel E. Cruickshank, A. F. R. Dewar, W. M. Dickson, Katherine M. Douglas, S. K. Drainer, W. Duncan, S. Dunn, J. G. Dyer, T. Dymock, C. R. Gibson, L. P. Gray, A. Henderson, J. Hinds, Elizabeth C. M. Jack, J. C. Cane, J. G. Kirk, L. Lamont, H. Leslie, P. L. B. Lorcet, Isabella K. A. Macdonald, Janet B. Macdonald, Elizabeth S. McFarlane, Margaret I. McGill, A. I. Maclean, J. C. MacMaster, D. C. M. Macpherson, A. H. W. Marshall, W. Marshall, A. Miller, J. W. Montgomery, T. Y. Muir, J. E. Naftalin, Frieda J. Oswald, A. L. Pirrie, J. A. Reddrop, J. F. Reilly, J. Riddell, R. Ritchie, A. B. Robertson, J. L. D. Roy, M. Sragowitz, W. Stewart, G. M. Stirling, C. Taylor, W. S. Thomson, J. B. Tyrie, D. Wilson, J. N. Wilson.

UNIVERSITY PRIZES.

Macewen Medal in Surgery.—Margaret W. Thomas.
Macleod Gold Medal (Surgery).—James F. Heggie.
*With high commendation for thesis.
†With commendation for thesis.

LIGHT AND HEAT IN MEDICINE AND SURGERY.—e Second International Conference (and Exhibition) on at and heat in medicine, surgery, and public health will held in London from Oct. 29th to Nov. 1st. The conence is organised by the *British Journal of Actinotherapy*, Featherstone-buildings, London, W.C. 1.

CHEMICAL INDUSTRY CONFERENCE.—A conference l be held from May 11th to 15th at the house of the stitution of Chemical Engineers, Great George-street, ndon, S.W. The communications to be made on May 14th lude a paper by Sir Alexander Houston on Water rification, and one by Mr. J. N. Coste on the Pollution tidal and Non-tidal Streams. On May 15th, in the morning, address on Scientific Research as applied to Industry, l be given by Sir Alfred Mond, and Sir John Russell, .S., will speak on the Part Played by British Workers he Application of Fixed Nitrogen to the Soil. A dinner l be held at Les Gobelins Restaurant, 1, Heddon-street, gent-street, London, W., on May 11th, after which Francis H. Carr will speak on Some Chemical Engineering pects of the Fine Chemical Industry. On May 12th a t will be paid to the Rothamsted Experimental Station, penden.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION. meeting of the Council of the Medical Women's Interional Association was held at Bologna on April 11th, was followed on April 12th, 13th, and 14th by an Open ting, which was attended by some 120 women doctors resenting 15 different countries. Spain and Sweden, ch have quite recently formed associations, were resented for the first time by fully accredited delegates, eight countries which were unable to send representas presented papers on one or both of the subjects selected discussion—viz. (1) medical measures for the protection children and young people in the various countries (2) diseases of the eye in relation to general medicine. ll 35 papers were received and were read in English, nch, German, and Italian. The Italian railway authori- gave special facilities and several Governments made nts to assist their delegates. Both the local committee the central Italian authorities had planned entertainnts on a generous scale. The Queen of Italy acted as roness and a "committee of honour" had been formed Signor Mussolini as President, and Signor Turati, retary-General of the Fascio, as Vice-President. The gural ceremony took place in the library of the old versity buildings, at which the Prefect, representing the lian Government, the Podestà of Bologna, and Prof. a, President of the Medical Faculty, spoke, and Lady rett, President of the Medical Women's International ociation, replied. An afternoon reception was given at Town Hall, and a dinner at the Fascist headquarters, n Miss Martindale, hon. secretary of the International ociation, replied to the complimentary speeches made. Saturday and Sunday expeditions were organised to enna and Rimini. Visits were also paid during the k to the principal hospitals of Bologna, in particular Istituto Ortopedico Rizzoli and the New Children's pital, the Ospedale Gozzadini. The meetings of the Asson were held in an historic setting, for the University had the historic Theatre of Anatomy in the Archiginnasio, h dates from the sixteenth century, for the purpose.

Mr. Neville Chamberlain (Minister of Health) has appointed Mr. A. Nevil Rucker to be his private secretary. Mr. D. C. L. Ward is to be private secretary to Sir Kingsley Wood.

INTERNATIONAL CONGRESS ON LIGHT.—The First International Congress on Light will meet from Sept. 4th to 6th at Lausanne, and on Sept. 7th at Leysin, where it will celebrate the twenty-fifth anniversary of Dr. Rollier's work. Prof. Rosselet, of Lausanne, will be the president. Communications and inquiries may be addressed to Dr. G. Murray Levick at 73, Harley-street, London, W. 1.

INTERNATIONAL INDUSTRIAL MEDICAL CONGRESS.—As we have already announced this congress will be held at Budapest from Sept. 2nd to 8th. A preliminary programme has now been issued and may be had from the hon. foreign secretary of the Council of Industrial Medicine, 12, Stratford-place, London, W. 1.

CHURCH MISSIONARY SOCIETY.—The annual meeting of the Medical Mission Auxiliary of this society will be held at the Central Hall, Westminster, at 7.15 P.M., on Wednesday, May 2nd. Sir Francis Champneys will take the chair, and the speakers will include Dr. C. M. Schaffter and Dr. J. H. Lechler. Tickets may be had from the superintendent, Loan Department, Church Missionary Society, Salisbury-square, London, E.C. 4.

OXFORD MUSEUM OF SCIENCE.—A scheme is on foot to found a museum illustrating the history of science and medicine in relation to academic studies at Oxford. The University has allotted part of the Old Ashmolean Building to the Lewis Evans Collection, and sympathisers with the scheme are invited to attend a meeting at the house of the Royal Society of Medicine, 1, Wimpole-street, on Wednesday, May 2nd, at 3.30 P.M.

MATERNAL DEATH-RATE.—The Queen's appeal for concerted action to reduce maternal mortality has resulted in the nine London Voluntary Maternity Hospitals forming a standing committee to deal with the subject. The committee will be a clearing-house for information, and it is hoped to associate the provincial maternity hospitals with the work. The hon. secretary of this committee may be addressed at 5, Cosway-street, London, N.W. 1.

A CHURCH HOSPITAL IN NEW ZEALAND.—A Church of England general hospital was recently opened at Christchurch, New Zealand, by the Governor-General of the Dominion. It is called the St. George's Church of England Hospital, has cost £40,000, has 67 beds, and is staffed by the Order of St. Elizabeth.

WEST MIDDLESEX POOR-LAW HOSPITAL.—The Brentford Board of Guardians is about to extend its hospital at a cost estimated at between £85,000 and £95,000. The plans provide for a new X ray department, a new maternity block, further ward accommodation, and other incidental works.

SHROPSHIRE ORTHOPÆDIC HOSPITAL.—This pioneer institution, founded in 1900 by Dame Agnes Hunt, last year had a daily average of 312 in-patients, and treated a total of 1020 patients. The income was £48,000, which slightly exceeded the expenditure, and an investment fund of nearly £5000 has been accumulated.

PRESENTATION TO A MEDICAL OFFICER OF HEALTH. Dr. Ashleigh Glegg, medical officer of health for Lindsey, Lincolnshire, who is about to take up a similar position under the East Sussex County Council, has been presented by his colleagues and by the staff of the department over which he has presided for 20 years, with a grandfather clock and a Sheraton book-case.

DONATIONS AND BEQUESTS.—Mr. Edward William Mellor, of Lytham, chairman of the hospital committee, has given £15,000 to the committee of Lytham Hospital for the completion of the rebuilding scheme, which has been retarded through lack of funds.—Mr. Albert Bland, of Penrith, left £500 to the Penrith Jubilee Hospital, £200 each to the Cumberland Infirmary, Edinburgh Royal Infirmary, and Dr. Barnardo's Homes, and £100 each to Siloth Convalescent Home, the Lord Mayor of London's Cripples Fund, and St. Dunstan's Hostel for the Blind, and the ultimate residue between the Cumberland Infirmary, the Siloth Convalescent Home, and the Penrith Jubilee Cottage Hospital.—Miss Thomas, of Llantysilio Hall, has given £1000 to the Llangollen Cottage Hospital to endow a bed in memory of her brother, the late Mr. John Thomas.—Lord Barnby, of Blyth Hall, near Doncaster, has given £10,000 to the fund in aid of Bradford's new infirmary.—Mr. Thomas Gallaher, J.P., left, among other bequests, £2000 to the Royal Victoria Hospital, Belfast; and £1000 to the Belfast Hospital for Sick Children.

COMMITTEE OF INQUIRY ON LEAD-ETHYL PETROL.—At the preliminary meeting of the committee which was held to-day the existing information regarding lead-ethyl petrol was considered and the question of procedure discussed. The next meeting of the committee will be held in Room 61, second floor, H.M. Office of Works, St. James's Park, S.W.1, at 11 A.M., on April 30th. Evidence will then be taken from the Air Ministry and the Anglo-American Oil Company. The proceedings at that meeting will be open to the public. The duty of the committee is to ascertain whether the use of ethyl petrol is in any way dangerous to health, and any persons wishing to give evidence on this question should communicate with the Secretary of the Committee, Ministry of Health, Whitehall, London, S.W.1.

CHARACTERISTICS OF CREAM.—A case was heard at Birkenhead on April 13th in which a dairyman was summoned for selling cream which was not of the nature demanded. The deputy town clerk, who prosecuted, referred to the new regulations prohibiting addition of preservatives to cream, and said that to meet this situation a new article known as "reconstituted cream" had been placed on the market. The public analyst said that a sample of this cream had not turned sour in a week, whereas natural cream would not have kept for 24 hours. What had been sold was in his opinion an emulsion of butter. The milk dealer who had supplied the defendant described the processes through which fresh milk passed in the separation of cream, and declared that the sample was not an artificial product; neither preservatives nor butter had been used in its composition. The magistrates dismissed the summons, finding the charge not proven. An application for costs was refused.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
TUESDAY, May 1st.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) Annual General Meeting: Election of Officers and Council for 1928–29. Cases: Mr. Rowley Bristow: Case of Bilateral Dislocation of the Patella. Mr. Whitchurch Howell: Case of Dislocation of the Shoulder. Other cases will be shown.
WEDNESDAY.—5 P.M., HISTORY OF MEDICINE. Annual General Meeting: Election of Officers and Council. Papers will be read dealing with the sources of Harvey, as follows: Prof. F. J. Cole: The History of Embryology. Dr. J. F. Prendergast: Galen.
THURSDAY.—8.15 P.M., TROPICAL DISEASES. Annual General Meeting: Election of Officers and Council. Demonstration: Sir Leonard Rogers: Climate and the Incidence of Small-pox, Cholera, and Plague; Forecasting Epidemics.
FRIDAY.—5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Annual General Meeting: Election of Officers and Council. Communication by Dr. R. Graham Brown (Brisbane). Discussion of cases shown at March meeting. Cases will be shown by Mr. Leslie Powell, Mr. Mollison, Dr. Dan McKenzie. 8.30 P.M., ANÆSTHETICS. Annual General Meeting: Election of Officers and Council. Discussion on Late Ether Convulsions. Opener: Dr. C. F. Hadfield.
SATURDAY.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.) Annual General Meeting: Election of Officers and Council. Papers: Mr. John P. Stuart: The Histopathology of Mastoiditis. Dr. R. Graham Brown (Brisbane): Case of Spherical Bulging of the Floor of the Third Ventricle, Secondary to Internal Hydrocephalus, and Simulating a Pituitary Tumour. Cases and Specimens will be shown by Mr. L. Graham Brown, Mr. E. D. D. Davis, Mr. H. Kisch, and others.

INSTITUTE OF HYGIENE, 28, Portland-place, W.
WEDNESDAY, May 2nd.—3.30 P.M., Dr. J. Strickland Goodall: Beginnings of Heart Disease in Children.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montague-street, Russell-square, W.C.
THURSDAY, May 3rd.—5 P.M., Naval, Military, and Air Force Hygiene Group of the Society. Discussion on the Problem of Diphtheria Control in Crowded Institutions to be opened by Surg. Comdr. S. F. Dudley, R.N.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
TUESDAY, May 1st.—5 P.M., Dr. E. P. Poulton: Experimental Study of Certain Visceral Sensations. (First Oliver-Sharpey Lecture.)
THURSDAY.—5 P.M., Dr. E. P. Poulton. (Second Oliver-Sharpey Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, April 30th, to FRIDAY, May 5th.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Tues., at 3 P.M., Clinical Demonstration by Dr. H. Cecil Bull.—ROYAL LONDON OPHTHALMIC HOSPITAL, City-road, E.C. Tues., at 1 P.M., Clinical Demonstration by Mr. Goulden. The above are free.—MAUDSLEY HOSPITAL, Denmark Hill, S.E. Course in Psychological Medicine, Lectures, Demonstrations, and Clinical Instruction.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Post-graduate Course in Dermatology, Clinical Instruction daily in the Out-patient Department. Practical Pathological Demonstrations will be arranged if desired.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Third week of post-graduate course in Medicine, Surgery and Gynæcology.—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. Wed., 5.15 P.M., third Lecture demonstration in series on Electrotherapy, given by Dr. C. B. Heald.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, N.W. Tues. and Thurs., at 2 P.M., Lecture-demonstrations in Tropical Medicine. Further particulars from the Secretary.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.
MONDAY, April 30th.—10 A.M., Dr. Dowling: Skin Dept. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Dept.
TUESDAY, May 1st.—10 A.M., Medical Registrar: Medical Wards. 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Dept.
WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. Simmonds: Surgical Out-patients. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.
FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 12 noon, Dr. Ironside: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Dept. 10 A.M., Dr. Owen: Children's Medical Out-patients.
Special Lectures 4.30 P.M., Tuesday, May 1st: Dr. Dowling: Skin Diseases due to Protein Sensitisation.
Daily 10 A.M., to 5 P.M. Saturdays to 1 P.M. In- and Out-patient and Special Departments. Anæsthetic Course. Operative Surgery Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham.
MONDAY, April 30th.—2.30 to 5 P.M., Medical, Surgical and Gynæcological Clinics. Operations.
TUESDAY, May 1st.—2.30 to 5 P.M., Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M. Medical, Surgical, and Ear, Nose and Throat Clinics. Operations.
FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.
On Wednesday and Friday, at 2.30 P.M., there will also be demonstrations of Eye and Surgical Cases by Mr. N. B. B. Fleming and Mr. E. Gillespie respectively.

THE LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, May 1st.—5 P.M., Dr. A. Whitfield: Eczema.
THURSDAY.—5 P.M., Dr. H. G. Adamson: Acne Vulgaris.
FRIDAY.—5 P.M., Dr. A. C. Roxburgh: Warts.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.
FRIDAY, May 4th.—4 P.M., Mr. A. Wylie: Treatment of Diseases of the Larynx.

GRESHAM COLLEGE, Basinghall-street, E.C.
TUESDAY, May 1st.—6 P.M., Sir Robert Armstrong-Jones: The Need of Change and the Medical Aspects of the Health Resorts of England and Wales. (First of four lectures on Physic.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.
TUESDAY, May 1st.—4.15 P.M., Dr. A. E. Barclay: Some Pitfalls in Radiology.
FRIDAY.—4.15 P.M., Dr. J. Wharton: Demonstration of Ophthalmological Cases.

Appointments.

ADAMS, E. G. B., M.B. Lond., F.R.C.S. Eng., and BLATHWAYT, L.R.C.P. Lond., M.R.C.S., have been appointed Medical Referees for Bath, &c., County Courts (Circuit 52).
MCGIBBON, JOHN E. G., M.B., B.Sc. Lond., D.L.O., Hon. Assistant Laryngologist and Aurist, Royal Southern Hospital, Liverpool.
Certifying Surgeons under the Factory and Workshop Acts: HARRIS, V. C. J., L.R.C.P. Lond., M.R.C.S. (Whitehaven) and JAQUES, E. H., M.B., B.S. Durh. (Haltwhistle).

Vacancies.

For further information refer to the advertisement columns.
Barnsley, Mount Vernon Sanatorium.—Asst. Tub. O. £456.
Basingstoke, Hants, Park Prewett Mental Hospital.—Second Asst. M.O. £450.
Bedford Borough.—M.O.H., &c. £900.
Belfast, Queen's University.—Prof. of Pathology. £900.

rmingham City Infectious Diseases Hospitals, Little Bromwich.—3rd Asst. M.O. £350.
lingbroke Hospital, Wandsworth Common, S.W.—Hon. Phys.
righton, Royal Sussex County Hospital.—Cas. H.S. £120.
istol General Hospital.—Pathologist and Curator of the Museum. £500.
istol Royal Infirmary.—Hon. Surg. in charge of Ear, Nose and Throat Dept.
rnley, Victoria Hospital.—H.S. £125.
rdiff, Glan Ely Hospital.—Two Res. M.O.'s. £350 and £200 respectively.
rlisle, Cumberland and Westmorland Mental Hospital.—Med. Supt. £850.
ntral London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—2nd Res. H.S. At rate of £75.
elmsford Administrative County of Essex.—Two Asst. County M.O.H.'s. Each £600.
lindale Hospital, Hendon, N.W.—Jun. Asst. M.O. £500.
xeter, Royal Devon and Exeter Hospital.—Asst. H.S. At rate of £100.
ji Government.—Dist. M.O. £500.
asgow, Woodilee Mental Hospital, Lenzie.—Jun. Asst. M.O. £300.
lden-square Throat, Nose and Ear Hospital, W.—H.S. £100.
llingly, Sussex, East Sussex County Mental Hospital.—Locum Tenens M.O. Seven guineas weekly.
ng Kong, University Faculty of Medicine.—Professor of Physiology. £800.
spital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.
ll Royal Infirmary.—Asst. H.P. At rate of £130.
eds Public Dispensary.—Hon. P. and Hon. S.
C.C. Mental Hospitals Service.—8th Asst. M.O. £300.
ince of Wales's General Hospital, Tottenham, N.—Clin. Asst.
therham Hospital.—H.P. £180.
yal Chest Hospital, City-road, E.C.—H.P. At rate of £100.
yal Free Hospital, Gray's Inn-road, W.C.—Asst. Phys. Also Ophth. Surg.
yal Naval Medical Service.—Surg.-Lieutenants. £453.
Bartholomew's Hospital.—Asst. P. to Children's Dept.
. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—3rd Anæsthetist. At rate of £25.
ngapore Municipality, Straits Settlements.—Asst. Municipal Health O. $8,400.
fford, Staffordshire General Infirmary.—H.S. At rate of £200.
ke Newington Metropolitan Borough.—Part-time M.O.H. £700.
ke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Anæsthetist, Hon. Asst. Aural S., and Hon. Asst. Orthop. S.
dan Medical Service.—M.O. £E720.
alsall General Hospital.—Sen. H.S. At rate of £200.
est Ham County Borough, Dagenham Sanatorium.—Asst. Res. M.O.
indsor, King Edward VII. Hospital.—Hon. Asst. P.
olwich and District War Memorial Hospital, Shooters Hill, S.E.—H.S. £120.
rk County Hospital.—H.S. £150.
rk Dispensary.—Res. M.O. £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Carnwath (Lanarkshire).

Births, Marriages, and Deaths.

BIRTHS.

UGHAN.—On April 22nd, at Cromer, the wife of Dr. D. Vaughan, of a daughter.

MARRIAGES.

RVIS—CHADWICK.—On April 19th, at St. George's Church, Hanover-square, W., Walter Harvey Gervis, F.R.C.S., to Sibyl Adelaide Rowsell, daughter of Mr. and Mrs. Walter A. Chadwick, of Croydon.

RSONS—LAING.—On April 14th, at St. James' Church, Sussex-gardens, London, Henry Frank Parsons, M.R.C.S., to Margaret Josephine Laing, daughter of the late Lieut.-Colonel Laing, and of Mrs. Laing, Stoke Bishop, Bristol.

KER EVANS—HORNE.—On April 17th, at Holy Trinity Church, Folkestone, Hugh Roker Evans, M.D., B.S., to Winifred Mary Zoffany, younger daughter of the late Mr R N. Kensey Horne, of Tasmania, and Mrs. Horne of Bouverie-square, Folkestone.

DEATHS.

KINS.—On April 19th, at Cathay, Alumhurst-road, Bournemouth, Francis Thomas Atkins, M.R.C.S., aged 77.

RBORD.—On April 19th, Edward Augustus Harbord, L.R.C.P., M.R.C.S., of Fairfax-road, N.W.6, in his 71st year.

RKWOOD.—On April 22nd, at Wrentham-avenue, N.W., John Kirkwood, M.B., C.M., aged 54 years.

RMAN.—On April 18th, at Brecon House, Wantage, Berks, Thomas Norman, M.R.C.S., L.R.C.P., aged 45.

NGER.—On April 17th, at his son's residence, Ruardean, Glos., William Stanger, F.R.C.S. Eng., J.P., in his 84th year.

B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

IN correction of a statement made by Dr. H. Hilliard in THE LANCET of last week (p. 793) Mr. Frank Coleman ites that it was his father, Mr. Alfred Coleman, and not nself who, jointly with Dr. Hilliard, introduced the nasa thod of administering nitrous oxide.

Notes, Comments, and Abstracts.

HOSPITAL LAW.

LIABILITY OF HOSPITALS AND THEIR PROFESSIONAL STAFFS FOR TORTS.

BY CAPTAIN J. E. STONE, *M.C.*, F.S.A.A.,
HON. SECRETARY, INCORPORATED ASSOCIATION OF HOSPITAL OFFICERS.

THE wrongs for which individuals seek redress consist of two main classes, those which result from a breach of contract, and those which arise from negligence or from wrongs committed, such being generally known as torts. A breach of contract consists in failing to do something that one has agreed to do, or in doing something that one has agreed not to do. A tort consists in doing something to the prejuduce of another which one ought not to do, or doing some rightful act but in a negligent or wrongful manner, time, or place, or by failing to do what ought to be done, thereby causing suffering or injury to another.

Contracts are quite definite in form when they are written and specifically indicate what is or is not to be done. Failure to live up to a written contract is quite easily determined and in general this is equally true with regard to certain forms of implied contracts which are not so definite as written contracts. In the case of torts there is considerable indefiniteness. When is a man injured in his property, person or rights? How much is he injured? Is the person causing the injury chargeable with negligence? What is negligence? All these are practical questions that arise in each individual case. The tendency of the law of torts is to give the plaintiff relief only if the defendant was culpable in some way. It must be proved that the defendant intended to damage the plaintiff, or that he might have avoided damaging him by using the proper amount of care, or that he was engaged in an unlawful act at the time the plaintiff suffered the injury. The standard of care required is that of ordinary prudence.

Contracts v. *Torts.*

There are, therefore, two phases of the question which require to be considered—liability for contracts and liability for torts. It may be said that, generally speaking, in the manner of contracts the hospital is liable for the acts of its authorised agents. If an officer of a hospital acting under authority engages or contracts to do anything, it is clear that the hospital is liable for damages caused by the failure to perform its part of the contract. If the officer proceeded without authority he would himself be liable. It is not an interference with the rights of charitable institutions to compel the authorities thereof to fulfil obligations freely and lawfully entered into.

The difference between actions based on contract and actions in respect of torts must be noted. If it can be proved that a hospital agreed to give certain services to a patient and failed to give them or is not competent to give them, it is possible that the patient would be able to recover damages, whereas in the absence of an express or implied contract he could not recover if the case was taken on the basis of liability for torts. Here it may be noted that in general an action for tort will lie against a corporation whenever it will lie against an individual, so the mere fact that a hospital is incorporated is not sufficient to relieve it from liability.

Since, however, most cases do not arise under liability for contracts, the main subject to be considered in connexion with the liability of hospitals is the liability for torts. It is perhaps some tribute to the general efficiency of the hospitals of this country that the reported decisions on hospital and professional negligence are very few. It has been said that the protection afforded to charitable hospitals in the past has been because of the public and the charitable service which they render. A second reason may be that since the funds of the hospital had been given in trust for a charitable purpose they could not be diverted to pay judgments, and they would be diverted even though the judgments might be paid from earned income, patients' contributions, &c. Another reason advanced was that patients accepting the charity of the hospital were thereby held to waive any right for damages which might be suffered by them. These contentions, however, cannot be upheld; in fact, exemption of liability on such grounds would work against the very interests which the donors had in making bequests to the hospitals.

What Constitutes Negligence?

As the liability of the hospital depends upon whether the doctor or nurse attending the patient has been guilty of negligence, it is necessary to consider what in law constitutes

negligence, for it is obvious that if an action against the person causing the injury fails, no action will lie against the hospital.

Negligence is a relative term, and conduct which would be considered negligent in some circumstances might well be considered as coming under the heading of due care in others. There are no legal degrees of negligence. It is negative rather than positive and implies the absence of the care, prudence, or forethought required. Exceptional obligations of care and caution may be required in certain cases, and in establishing negligence it must be shown that an existing duty has not been performed. That is, the party complaining must point out how the duty arose which is alleged to have been neglected. After the duty has been pointed out, the failure to perform it must be proved—that is, the existence of the negligence. The presumption is that the individual will perform his duty until the contrary is shown.

One may become liable in tort by actually doing to the injury of another something that should not be done; by doing something the individual may rightly do, but wrongfully or negligently doing it by such means, at such time, or in such manner, that another is injured; or by neglecting to do something which ought to be done, whereby another suffers an injury. The first is an active wrong which may be done by the party in person or by some other person for whose conduct generally or under the particular circumstances he is responsible. A person is always responsible for the conduct which he counsels, advises, or directs, and for whatever naturally results from his counsels.

Professional Skill.

Of course, unreasonable requirements cannot be enforced upon a hospital or any member of its professional staff. Neither a hospital not a physician is liable for a failure to give the best that the world affords. They are required to give the best at least that the facilities and medical knowledge of the immediate community afford. A hospital in a small town remote from great medical centres would possibly not be held responsible for as many things as would one centred in a metropolitan area. If the hospital does the best it can with the lights and facilities it has, the rule of reason is satisfied; hospitals and their staffs cannot be held liable for acts or omissions when in the exercise of their judgment they did what they considered best for the patient—e.g., failure to perform an operation, although a post mortem should disclose that an operation would have saved the life of a patient, should not create liability. Lack of supreme knowledge or mistake in medical judgment cannot create liability, unless in any case it is proved that the circumstances were such that there was negligence.

The law may be stated thus: A physician or surgeon is in the same position in this respect as any other professional man; he does not undertake that he will perform a cure, nor does he undertake to use the highest possible degree of skill, but he does undertake to bring to his task a fair, reasonable, and competent degree of skill. A physician or surgeon is not answerable merely because some other practitioner might possibly have shown greater skill and knowledge or even used some greater degree of care, so long as he showed due care and a competent degree of skill and knowledge. In order to give rise to criminal liability the negligence must be of such a nature that it can be brought under the heading of wilful negligence. The law extends to the medical profession the greatest possible protection, and if a member of the profession acting bona fide takes an erroneous view of a case or commits an unintentional mistake, he cannot be made criminally liable, whatever the consequences of his error may be. So if a surgeon bona fide and honestly exercising his best skill to cure a patient performs an operation which causes the patient's death, he is not guilty of manslaughter. The authorities are clear that in a prosecution for criminal negligence, the question whether the accused was or was not a duly qualified practitioner is not in itself a material element in ascertaining his liability.

A less degree of incompetence or negligence will support an action for damages. In such a case the question is not whether there was a wilful intention, but whether the injury complained of was due to the absence of reasonable care and skill. In one such case damages were recovered by a patient who lost his hand in consequence of improper treatment founded on a mistake as to the nature of the injury.

TREATMENT OF GUN-SHOT WOUNDS BY AMBROISE PARÉ.

IN publishing last week the translation of an article on the Treatment of Gun-shot Wounds and the Improvement Thereof by Ambroise Paré, we should have stated that the original paper was contributed by Prof. Theodore Meyer-Steineg to the German edition of the Cartellierii Festschrift. This book was published by Böhlau at Weimar in 1927, price 10 marks.

SWISS CLIMATES.

To the Editor of THE LANCET.

SIR,—I should be grateful if any of your readers who ha a knowledge of Switzerland could recommend as a permane residence the most suitable locality for a sufferer from gou arthritis and occasional bronchitis.

I am, Sir, yours faithfully,

April 23rd, 1928. A. M. C.

CONVALESCENT SERUM IN POLIOMYELITIS.

DURING an epidemic of poliomyelitis in Sweden in 19 Dr. H. Davide [1] inoculated a number of exposed villag with serum from convalescents. His method was to dr off blood at about the tenth day, when the fever had d appeared, and after a Wassermann test the serum w separated, mixed with 0·5 per cent. carbolic acid, and p up in 5 c.cm. ampoules. He considers that there is danger of transmitting the disease with serum, as all t evidence is against the presence of the virus in the bloo Selecting an area which his observations told him was like to be visited by the epidemic, he inoculated 73 persons und 25 years of age, and also observed 84 others as contro Among his controls 14 were attacked, either by the typic or by the abortive form; of the inoculated group one alo caught the disease. This was a boy of 4, who was presumab infected before inoculation, for the onset occurred only hours afterwards. He suffered from stiffness of the ne and possibly from pyrexia (though his temperature w never taken) for 12 hours, after which he complete recovered. Four inoculated infants escaped, though th young nurse succumbed.

Experiments [2] on the therapeutic use of serum have be made in Roumania with serum prepared by the Paste Institute by Pettit's method. The doses were much larg than Dr Davide's, being 20 c.cm. intrathecally and 20 c.c intramuscularly, repeated after four to six days. Ve severe cases are reported to have been checked, but detailed reports are given.

TREATMENT OF HYDROCYANIC POISONING.

Dr. J. A. Pique [3] recently reported a case of poisoni by potassium cyanide treated by intracardiac injection sodium hyposulphite. A child of 19 months poisoned itse with cyanide whilst crawling on a verandah which had be sprinkled with the drug to kill the ants. The mother once gave it sugar in water and within 15 minutes broug it to the hospital. On the way it vomited and becan unconscious. It showed the normal signs of cyani poisoning on admission, was unconscious, and convuls with slight opisthotonos; the respirations were 7 per minut and no pulse was detected. As the case seemed despera Dr. Pique injected into the heart 15 c.cm. of 10 per cer sodium hyposulphite solution and 1 c.cm. of adrenal 1/1000, giving also oil of camphor and caffeine by the ski The effects were immediate; in three minutes the pul reappeared, the breathing became free, and convulsio ceased. Lavage produced food with a smell of bitt almonds. Though the case is a remarkable one, it cann be held to prove the value of sodium hyposulphite; indee the rapid efficacy of the treatment suggests that it w the adrenalin which turned the scale, assisted by the fa that sugar had already been given. Taylor [4] mentio the value of sugar and says that sodium thiosulpha has been recommended; the hyposulphite seems not have been used in England but has been recorded as value in foreign journals. Whatever view we may take the value of the drugs employed, the success of the trea ment in such a desperate case indicates very strongly t desirability of employing the intracardiac route and t same combination in similar emergencies.

QUEEN ALEXANDRA MEMORIAL.—The appeal f the Scottish National Nursing Fund Memorial to Que Alexandra has now been closed. The sum at prese declared is £87,000, but the final figure is likely to rea about £90,000. The original proposal, launched in 192 was for £150,000, to be used in augmenting the funds of t Scottish Branch of the Queen's Jubilee Institute for Nurs at Edinburgh, less 25 per cent. for local nursing service The highest individual subscription was £1,000, so that t great bulk of the sum raised was obtained in small amount

Observations
ON
PURPURA OF THE URINARY TRACT

Based on a Presidential Address delivered before the Section of Urology of the Royal Society of Medicine

BY FRANK KIDD, M.CHIR. CAMB., F.R.C.S. ENG.,
CONSULTING SURGEON TO ST. PAUL'S HOSPITAL FOR DISEASES OF THE GENITO-URINARY ORGANS AND SKIN.

(*With Coloured Plate.*)

SINCE 1912 I have met with a considerable number of cases of purpura of the urinary tract and for my present purpose have analysed 24 of them.

Purpura is characterised by spontaneous extravasations of blood into the skin, mucous membranes, joints, retinæ, and interstitial tissues. The resulting lesions in skin or mucous membrane are called petechiæ. These are blood-red or purple spots and patches which may be rounded, ovoid, linear or irregular in shape, and vary in size from that of a pin's-head to patches nearly half an inch in diameter. Occasionally they assume the character of large bruises or even hæmatomata. They do not disappear on pressure, but in a few days they turn brown and then fade away altogether. Hæmorrhages can also be observed in the interstitial tissues of the viscera in cases of purpura or "the hæmorrhagic disease," as it is often called. That hæmaturia is of common occurrence in cases of purpura has been recognised for many years, but it is remarkable that petechiæ in the bladder should have escaped recognition by cystoscopists for so long.

I have included in these 24 cases only those in which it has been possible to prove the condition to be one of purpura. All of them came up as cases of hæmaturia for diagnosis of the possible cause. Many of them presented petechiæ on the skin. The majority presented petechiæ in the bladder as viewed by the cystoscope. Some of them showed petechiæ in the mucous membrane of kidneys removed for dangerous hæmaturia. Some presented joint swellings, presumably due to extravasation of blood into the joints. Others had bleeding from the bowel, nose, or teeth, and one had nephritis. During the same period I have met with a number of cases of hæmaturia in which the bleeding observed to come from one or both kidneys has cleared up, and the clinical course has suggested that the condition was one of purpura of the kidney. As in such cases absolute proof has not been possible, they have not been included in the analysis. But I feel sure that such purpuric bleeding from the kidney is not uncommon, and explains many cases of painless hæmaturia. A purpuric bladder is always painful, but a purpuric kidney usually causes no pain.

The observations suggest that purpura of the urinary tract can be classified into three main clinical groups :—

(1) *Purpura simplex*, which exhibits a single or a few mild attacks of hæmaturia, soon clearing up and not thereafter repeated.

(2) *Purpura recurrens*, which exhibits repeated severe attacks over a period of years and which may gradually react to treatment.

(3) *Purpura fulminans*, where one or two severe attacks appear within a short time of one another and lead to death within a few weeks or months.

Purpura of the urinary tract appears in two clinical guises :—

(1) *Vesical*, with sudden onset of profuse painful hæmaturia, but with little or no systemic disturbance. The diagnosis can be readily made by immediate cystoscopy, and the prognosis is good.

(2) *Renal*, with sudden onset of profuse painless hæmaturia and little symptomatic disturbance apart from severe loss of blood. The cystoscope reveals blood pouring from one or both kidneys. Pyelograms are normal. The diagnosis is made in some cases by nephrectomy, in others by the presence of purpura elsewhere in the body, by the examination of the blood, or by the tourniquet test. Often the diagnosis can only be provisional.

DIAGNOSIS.

For a long time it has been the custom in urological circles to talk of "essential hæmaturia," a term which begs the question and obstructs research. I prefer to speak of "cases of hæmaturia of which the cause has not been determined." I believe that a number of the cases usually labelled essential hæmaturia are in reality cases of purpura of the kidney, that purpura is not at all an uncommon cause of hæmaturia from the bladder or the kidneys, and that its nature is missed either because cystoscopy is not carried out at an early period when petechiæ could be observed in the bladder, or because, where pain and petechiæ in the bladder are absent, there is usually no occasion to remove one kidney, and so the purpuric nature of a bleeding kidney cannot be determined by direct observation. In all cases of unexplained hæmaturia a rigid examination of the skin, joints, retinæ, and the hæmopoietic system may reveal the true nature of the case. It is the rule for the patient to have failed completely to notice even quite large petechiæ on the skin, so that these need to be sought for specially. The diagnosis can be readily made if cystoscopy be carried out within a day or two of the bleeding and if the bladder is then seen covered by petechiæ. In these cases the hæmaturia is painful. Neoplasm is excluded if an early cystoscopy reveals profuse bleeding from one kidney, and a pyelogram shows a perfectly normal outline to the pelvis of that kidney. In these cases the hæmaturia is usually painless. If the blood shows a marked diminution or absence of platelets, prolonged bleeding time, normal clotting time, or the presence of a characteristic non-retractile fibrin in the clot, then the diagnosis of thrombocytopenia purpura can be confidently made. If petechiæ are observed in other parts of the body the diagnosis is at once apparent. The static resistance test of Hess may throw light on the diagnosis. A tourniquet is applied for three minutes to one arm; in cases of purpura this should produce purpuric spots on the skin of the arm. Even so, a large number of cases must remain not proven, but if it is once recognised that painless purpuric bleeding from one or both kidneys is not uncommon, then the minds of urologists will be set at rest. It has been the fashion to insist that the commonest cause of unilateral hæmaturia is a neoplasm, but it is doubtful if neoplasm of the kidney is as common as has been taught. With this teaching in his mind the urologist has been rendered too anxious, and has been inclined too readily to remove a bleeding kidney in case he might be missing an early neoplasm. The results of removing a large late neoplasm of the kidney are on the whole disappointing, and the only chance of permanent cure resides in making the diagnosis of malignant kidney before the tumour has become so large as to be palpable. Again, it is in the highest degree unwise to open a kidney at operation to see if it contains a neoplasm. If it does and if it has been opened, recurrence within a year or less is almost invariable. If a surgeon is to get permanent results and any real cures of neoplasms of the kidney, he must make up his mind as to the diagnosis before he starts the operation, and must remove the kidney intact within its perinephric and fatty capsule. If the capsule is torn—apart from any incision of the kidney—an early recurrence is the rule rather than the exception. These considerations have led urologists in the past 20 years to remove a large number of kidneys suspected of neoplasm when none was present. Many of these cases were in all probability cases of purpura.

The remedy lies in recognising that neoplasm of the kidney is comparatively rare and is by no means a common cause of hæmaturia. Pyelography, repeated several times if necessary, should invariably be carried out in all cases of unilateral hæmaturia. If the pyelogram shows no evidence of neoplasm it

should be trusted and the patient kept under observation and the kidney left alone. Provided the hæmorrhage is not alarming no harm can be done by waiting and taking repeated pyelograms at intervals of two to three months. In some cases the hæmorrhage is so severe as to endanger life, and it will be necessary to operate. In seven cases I have had to remove the kidney for grave hæmaturia due to purpura, and in one of my cases of purpura of the bladder a bleeding kidney had been previously removed by another surgeon. I am certain that I have left in situ quite a number of purpuric kidneys, where I have observed unilateral hæmaturia and repeated pyelograms have been negative. In some cases the hæmaturia has been repeated several times, in others it has never been repeated. I have also removed a certain number of profusely bleeding kidneys wherein no purpuric lesions could be seen in the pelvic mucous membrane, but where on section a certain amount of interstitial hæmorrhage was apparent lying between the tubules. I believe that these cases should be classed in the same group and should be considered as instances of interstitial hæmorrhage into a viscus caused by purpura or "the hæmorrhagic disease."

Differential Diagnosis.

The differential diagnosis from other causes of vesical bleeding, especially hæmorrhagic or tuberculous cystitis, is readily made by the cystoscopic observation of petechiæ scattered throughout the bladder, in between which the mucous membrane appears healthy (Fig. I.). The differential diagnosis from other causes of renal bleeding is more difficult. Common causes, such as infection by the colon bacillus, or the tubercle bacillus, calculus, and hydronephrosis, are detected by the usual routine methods. Less common causes of renal bleeding are a high systolic blood pressure, which may be associated with petechiæ on the skin, with or without "granular" kidney; the various anæmias and leukæmias; and polycythæmia. The size of the spleen should be estimated by palpation, percussion, and X ray examination. It must be clearly emphasised that in all cases of hæmaturia a most rigid and exhaustive study must be made of the blood, including the clotting time, bleeding time, and a platelet count. By this means not only can cases of thrombocytopenia be marked off and if necessary treated by splenectomy, but it may also be possible to separate off cases of aplastic anæmia, pernicious anæmia, leukæmia, cholæmia, and early cases of polycythæmia. I have met with three cases of polycythæmia where profuse unilateral hæmaturia was the earliest symptom. In the first I removed the bleeding kidney, in the other two, taught by experience of the first case, I was able to make the diagnosis by examination of the blood.

Scurvy may be mistaken for purpura and is in all probability an instance of a true purpura where the cause is known—namely, vitamin C deficiency due to lack of fresh fruit and vegetables. The platelets are not deficient in numbers. Hæmophilia can usually be distinguished by its hereditary nature, its history, and the fact that the clotting time of the blood is delayed, whereas the clot itself is normal and there is no deficiency of blood-platelets. Hæmoglobinuria is distinguished by expert examination of the urine. One of the commonest causes of profuse hæmaturia is acute pyelitis. The sudden onset with a rigor and high fever, the presence of pyuria as well as bacilluria, the enlarged tender and painful kidney, and the quick response to alkaline treatment should differentiate pyelitis from purpura.

Blood Platelets in Relation to Purpura.

Denys, a Belgian histologist, called attention in 1887 to the fact that in some cases of purpura there was a low platelet count. Hayem in 1890 confirmed this and made the following observations:—

(1) That there was no appreciable change in the red blood corpuscles.

(2) That there might be a considerable diminution in the number of platelets and that those present might be of "giant type."

(3) That there was no constant change in the leucocytes

(4) That the blood coagulated in normal time, but tha the fibrinous reticulum developed as fibrin of unusual siz did not retract from the walls of the glass vessels into whic the blood had clotted, and did not squeeze out the seru from the clot.

In 1912 Duke called attention to an addition fact—that though the clotting time was normal, ye the bleeding time of a pin-prick might be considerabl prolonged. A prick which should cease to bleed i three minutes might bleed for as long as an hou He studied the platelets in 31 cases and in 14 he foun a platelet count below 65,000 per c.mm. of blood, th normal being 200,000 to 300,000. If the platel count was below 10,000 the case was severe, if belo 1000 very severe. Ledingham and Bedson advance these observations further by work on guinea-pig rats, rabbits, and goats. They showed that a antiguinea-pig platelet serum produced purpura i guinea-pigs and also an early extensive fall in th platelets; if recovery ensued the platelets rose agai to normal. The effect was specific and was no produced by heterologous sera. An antiplatel serum had no effect on the leucocytes and a antileucocyte serum had no effect on the platelet yet both would produce a partial clumping of the re blood cells. Antiplatelet serum contains a specif antibody for platelets, and this supports the vie that platelets are independent elements of the bloc and bear no relation to the red cells or leucocyte Platelets appear to supply an indispensable thromb genetic element, and if this is reduced the animal liable to purpura. These results have since bee confirmed by Lee and Robertson, Gottlieb, ar Watabiki. Duke produced purpura in rabbits b repeated injections of diphtheria toxin and benzo which destroy platelets.

Purpura in man has been noted after injectio of salvarsan (Anwyl-Davies, Labbé and Langlo Wydooghe and Ferond). It has also been observed benzol poisoning (Anderson, Boyd, and Jackson, ar in iodine poisoning (Stephen Mackenzie). I ha observed it in two cases after injections of strept coccal vaccine. General purpura has been provok in rabbits by repeated doses of X rays (Lacassagn Lavedan, Léobardy). Frank again called the attenti of clinicians to the low platelet count in some cases purpura and suggested the term thrombocytopen for this class of case. Kaznelson observed a case purpura with thrombocytopenia where the spleen w enlarged. Arguing that the enlarged spleen might b actively destroying the platelets, he had the sple removed at operation by Scloffer, with complete cu of the patient. In 1918 and in 1919 he report further cases of successful splenectomy for this troub Hitzrot reported further cases and Edwin Be reported five cases of splenectomy for this class purpura, four of which were successful, and states th some 50 cases have now been reported in the literatu of splenectomy for thrombocytopenia with t hæmorrhagic diathesis or purpura. He considers th splenectomy can only be of avail in purpura recurre and not in purpura fulminans. In some of Bee cases the number of platelets increased after splene tomy, but dropped again in course of time; t hæmorrhages did not recur, however, and the patie appeared to be cured. Brill and Rosenthal noted t same after two cases of splenectomy. This fits with the observation of Service, who cured a case diabetes with low platelet count of the bleedi tendency by insulin and repeated blood transfusio Yet the blood-platelets remained low. Beer cou produce no evidence by examining the blood fr the splenic vein and artery that the spleen did destr platelets. Yet the removal of the spleen appears remove the tendency to hæmorrhage.

The Problem of Causation.

The heart of the problem still awaits solutio Brill and Rosenthal suppose that the spleen must some way cause the capillary walls of the bloc vessels to become sensitive to circulating toxi They say the platelets are not directly concerned

ausing the bleeding tendency. Beer suggests: 1) that there is a defective formation of platelets n the bone-marrow; (2) that circulating toxins estroy the platelets; (3) that the spleen destroys he platelets. None of these hypotheses covers all he facts. Spence has analysed 101 published cases of plenectomy for purpura. The bleeding tendency was ured in 69 and 21 died of the operation. He agrees vith Beer that splenectomy is only suitable for chronic elapsing cases. He divides the cases into three types n an ingenious attempt to formulate a theory of the ction of the spleen and reticulo-endothelial system n causing purpura. Giffin reports from the Mayo linic a number of cases of unusual types of hæmorhagic disease which serve to show that the problem f causation can best be solved by further research on linical cases. Conner and Bumpus conclude that here is not enough evidence at hand to prove that ssential hæmaturia is ever localised purpura, or due o a deficiency of blood-platelets, but the evidence ather suggests that this is true in some cases.

Local Infective Foci as a Cause.—It appears that here there are several different types of purpura, vith differing causation, but that in a number of cases a local focus of infection can be found if carefully ought, and its removal may cure the tendency to æmorrhage. The infection is most likely to be due o a streptococcus, but it may probably be due to any acterium, such as the colon bacillus, *Staphylococcus ureus*, pneumococcus, meningococcus, and the viruses f small-pox or measles. The local focus is most likely o be found in the teeth, tonsils, accessory air sinuses, iddle ear, or bowel. Bradburn reports a case of urpura cured by removal of septic teeth, and in a umber of the cases reported above and in those reported y Moreland McCrea the removal of septic teeth or eptic tonsils appeared to lead to a cure. In three of ıy cases purpura developed the day after the extracion of septic teeth, and in another after the removal f septic tonsils. Similar happenings have been eported by Kleeblatt (teeth), by Robson after the emoval of a rusty nail from the foot, by Kretschmer fter an operation for osteomyelitis, by Clay and olden after an operation for mastoiditis. Wadsworth eported a case of bilateral renal calculi with streptoocci and pyuria that developed purpura. I have bserved two cases of severe purpura in women ssociated with pyelitis due to the colon bacillus. n each case renal lavage cured the condition.

Classification.

Attempts to classify the purpuras too closely on a linical basis seem apt to lead to confusion. The mplest way to look at the condition is to realise that urpuric bleedings in any situation are only a symptom nd not a disease; that adequate classification will nly become possible when a large number of different auses that may give rise to the symptom of purpura ave become adequately recognised and proved; hat purpura in the skin can be associated with leedings into any mucous membrane or viscus, and hat the cases can fall clinically into three main groups: mple, recurrent, and fulminating. The best classication so far attempted appears to be that of Brill nd Rosenthal. This has been somewhat modified elow in the light of further clinical observations made n the last few years. In the first place, all cases of urpura can be classified by an examination of the lood into two main groups: (1) the thrombo-ytopenic, (2) the non-thrombocytopenic. In both is possible that injections of sera, blood, and roteins may do good, but it is only in the first group hat splenectomy has so far been employed with uccess.

In the second place, cases of purpura may be classified nto: (1) those in which a proximate cause is pparent and which may be removable; (2) those in hich the cause is unknown.

(1) Those in which a proximate cause is apparent.

(*a*) *Bacterial Poisons.*—Streptococci, staphylococci, pneuococci, meningococci, small-pox, measles, acute rheumatism, cal infective foci in teeth, tonsils, sinuses, middle ear and owel, trench nephritis (Stevens and Peters), pyelitis.

(*b*) *Chemical Poisons.*—Turpentine, quinine, belladonna, iodine, benzol, arsenic, salvarsan, snake venom.

(*c*) *Intrinsic Metabolic Poisons.*—Cholæmia, anaphylactic agents.

(*d*) *The Poisons Generated in Diseases of the Hæmopoietic System.*—The leukæmias, aplastic anæmia, pernicious anæmia, Banti's disease.

(*e*) *Vitamin Deprivation.*—Scurvy, rickets.

(*f*) *Functional Changes in the Walls of the Blood-vessels.*—Schindler has reported two cases in victims of religious mania which were cured by suggestion.

(*g*) *Changes in Blood Pressure.*—High blood pressure, senile purpura, purpura of the menopause.

(2) Those in which the cause is unknown, so-called idiopathic purpura or the hæmorrhagic disease.

Prognosis and Treatment.

In the 24 cases analysed the 16 vesical cases all recovered quickly, four of the nephrectomy cases recovered completely, two of the nephrectomy cases still suffer from mild recurrent attacks of hæmaturia but are definitely improved, and two died in a few months despite nephrectomy. Stephen Mackenzie states that most cases of purpura recover in the end, but that 15 per cent. die chiefly from nephritis, endocarditis, or loss of blood.

In 8 of 24 fulminating cases and cases with grave hæmaturia it was necessary to resort to nephrectomy. In the mild cases, especially in children, the treatment most likely to prove efficacious seemed to be to give 25 c.cm. of antistreptococcal serum by the mouth every 48 hours for two or more doses, and to attend to the teeth and tonsils. The serum when given by the mouth did not appear to lead to anaphylaxis, and it certainly produced as profound an effect as when given under the skin. Calcium lactate appeared to have no ameliorating action. Possibly an active preparation of parathyroid gland with calcium might give better results. In all cases it is probably wise to give large doses of alkalis according to Blum.

Most marked benefit was obtained in the majority of relapsing cases by giving antistreptococcal serum by the mouth three times in a week every two or three months. At the same time all teeth shown by the X rays to be diseased were dealt with in easy stages, and the tonsils, if diseased, were enucleated. In one case removal of a heavily infected appendix cured the trouble, and in two others an intestine heavily infected with *Streptococcus fæcalis* received treatment, and with the diminution of the streptococcus in the stools the tendency to hæmorrhage disappeared.

Autogenous streptococcal vaccines were used in two cases. In small doses they did no harm, but effected no real improvement. If the dose was too large it at once produced an attack of purpura.

If no local focus of bacterial infection can be detected in the teeth, throat, upper air passages, and bowel, resort should be had to the more severe methods, which are, in order of increasing severity: auto-serotherapy, direct transfusion of homologous blood, protein shock therapy, and splenectomy.

Effect of Serum.

Weil, in 1905, showed that in cases of hæmophilia the blood could be rendered normal for a time by subcutaneous injections of normal horse serum; surgical operations could be safely carried out in hæmophiliacs after the injection of horse serum, and bleeding could be stopped in the same manner after operation in hæmophiliacs who had not previously had injections of serum. Nolff in 1909 showed that bleeding in hæmophiliacs and in hæmoglobinurics could be stopped by subcutaneous injections of peptone. Widal found that similar results could be obtained in some cases of purpura; that injections of serum and peptone stopped hæmorrhage at once, and if repeated might cure these conditions.

In a number of the cases reported above subcutaneous injections or oral administration of normal horse serum or of antistreptococcal serum were given, and in the majority quickly checked the hæmorrhage. Repeated injections greatly diminished the severity of the attacks and rendered recurrences less frequent.

Yet in some cases, despite repeated injections, the attacks continued to recur, although in a less severe form and at longer intervals.

Widal announced later that the action of the serum or peptone was probably non-specific and acted by producing a colloido-clasic crisis; that any foreign protein introduced into the circulation might produce a favourable result, even the injection into a muscle or under the skin of the patient's own blood, which apparently acts as a foreign protein (auto-sero-therapy). However these injections may act, there can be little doubt that they should be the second line of attack in dealing with purpura. Favourable results have been reported in purpura after the subcutaneous or intramuscular injection of horse serum (Stern, &c.), antistreptococcal serum, peptone, sterilised milk (Gram), and even the patient's own blood (Widal, Emsheimer, Howard). The results are not, however, uniformly successful. Resort may then be had to intravenous injections of whole human blood from a suitable donor. Should such treatments prove ineffective, then splenectomy should be considered, as brilliant results have been reported in a number of cases. Splenectomy has so far been reserved for cases of true thrombocytopenia and should only be employed in severe recurrent cases, not in simple or fulminant cases. Giffin's recent work suggests that splenectomy may sometimes be advisable when there is no thrombocytopenia.

Other Remedies.

Some writers have reported good results from subcutaneous injections of adrenalin in repeated doses. Others state that small doses of turpentine may do good. Morris reported a case in China in 1916 cured by emetine hydrochloride; another successful case was reported by Plantier, of Algiers. Blum and Szabo advise large doses of alkalis in cases of bladder purpura to render the urine alkaline. They state that urine contains pepsin which in acid urine may cause digestion of the hæmorrhagic areas and the formation of "peptic" ulcers. The alkali is said to render the pepsin inactive. Oppenheim states that he cured a case by radiation with a quartz lamp. Suggestion has been employed in the cure of hysterical cases (Schindler).

Illustrative Cases.

Purpura Simplex; Purpura of the Bladder.

Case 1.—A girl, aged 12, admitted to the London Hospital on Nov. 30th, 1910, stated that on the evening of Nov. 28th she felt a sudden desire to pass water, and during the act experienced a sharp stabbing pain, starting in the left iliac region and spreading into the vulva. Between 8 P.M. and 9.30 P.M. she passed water four times, each time noticing a similar pain, which lasted only as long as water was passing and ceased at once at the end of the act. At 9.30 P.M. she passed water again, and this time inspected it. It was full of blood. An aching pain came on in the left iliac region when she went to bed, and lasted all night and the whole of the next day. Urine was passed once in the night and five times during the next day until the time of admission into the hospital at 5 P.M. on Nov. 30th.

Previous Health and Habits.—Diphtheria five years ago, otherwise no serious illness. No hæmophilia, no scurvy. The patient lives in Poplar, amongst poor and unhealthy surroundings. She has had a sore-throat for some days before the onset of the hæmaturia, and has felt "out of sorts."

Examination.—The patient looks ill and is pale and anæmic. The temperature is normal, pulse- and respiration-rate are normal, the tongue clean and moist, the heart, lungs, and alimentary system normal. There is follicular tonsillitis on the left side, and some slight enlargement of the glands on the left side of the neck, which are tender to the touch. The skin shows no petechiæ, and the gums are healthy. There is deep tenderness over the bladder region, especially on the left side. The urine is full of blood-clots, and contains bright red blood diffused throughout.

The patient was at once taken into hospital and put to bed. By the next morning the bleeding had ceased and the pain had disappeared.

Dec. 1st, 1910: X ray examination of bladder and kidney areas shows an absence of stone shadows. The urine is clear to the naked eye, 38 oz. in 24 hours, the reaction acid, specific gravity = 1021, no albumin, urea 2·5 per cent. Hæmo-renal index (electrical resistance of urine and serum) = 1·5 (normal 2).

Dec. 2nd, 1910. *Cystoscopy.*—The bladder was filled wi 8 oz. of oxycyanide of mercury solution, 1 in 4000. Bo ureters appeared healthy. The bladder wall for the great part appeared pale and healthy, but scattered irregular over fundus and trigone were patches of submuco hæmorrhages varying in size from a pin's head to a sixpenc The patches were of all shapes and sizes, some linear, son stellate. The greater number were scattered over the fundu There was no ulceration and no sign of miliary tubercle I came to the conclusion that I was either dealing with purpuric condition of the bladder wall, or that I had caug a primary blood infection of tuberculosis at its very onse

On Dec. 5th and again on Dec. 6th a 24-hour specimen urine was examined for tubercle bacilli and for pus cells, b none was found. The Pirquet tuberculin reaction w positive.

The urine remained clear until Dec. 9th, when anoth attack of pain and bleeding came on exactly similar to t first one. This lasted two days and then cleared up co pletely. Throughout the whole time the patient was hospital the temperature remained normal, and there we no signs of constitutional disturbance except that t patient felt below par.

Dec. 15th, 1910. *Cystoscopy.*—No pain, no increase frequency, no blood for four days. The picture had chang completely; the bladder was quite healthy again save f faint patches like fading bruises on the wall of the fund and also about an inch above the middle of the bar Mercier a small fading hæmorrhagic patch in which a sm blood-vessel ran and was lost.

Dec. 16th, 1910. *Blood Examination.*—Coagulation tim five minutes. Red blood corpuscles 5,000,000. Hæmoglobi 85 per cent. Colour-index, 0·8. White cells in norm proportions.

Course.—Calcium lactate grs. 10 three times a day w administered for a week, and the patient left the hospital Dec. 19th restored to health, and has since had no return the bleeding.

*Purpura Simplex; Purpura of the Kidney.**

Case 2.—A woman, aged 38, was admitted under m care at the London Hospital on Dec. 18th, 1916. S stated that three weeks previously she had develop active incontinence of urine and strangury. Six wee later the strangury had suddenly ceased and she had beg to pass large quantities of blood in her urine. This h continued on and off ever since.

The patient appeared wasted and anæmic, but exhibit no physical signs. The urine contained a large quantity blood and numerous coliform bacilli in pure culture, but r pus or casts. The blood showed no changes except those secondary anæmia. Cystoscopy revealed blood pouring o of the right ureter in cascades. The urine from the le kidney was natural. X ray examination was negative.

On Dec. 19th, 1916, the right kidney was removed, as a early tumour was suspected. Examination of the kidn showed large purpuric spots and patches under the muco membrane of the pelvis. No other changes could be discover except slight degeneration of the cells of the collectin tubules.

Purpura Recurrens; Purpura of the Kidney and Bladder.

Case 3.—A single woman, aged 40, was examined May, 1925. Her doctor stated that in June, 1924, she ha suffered from strangury, pain in left kidney, and bacteriuri and in November, 1924, had had a second attack. Sinc January, 1925, there had been increased frequency, pain o passing water, and constant aching pain in left kidney. Fo six weeks she had been confined to bed with slight feve 99·5° F., and profuse sweating, daily growing more ill an anæmic. No pus or bacteria could ever be found in urin Recently she had had profuse hæmaturia, which led h doctor to call for further advice.

On examination the left kidney was considerably enlarge and tender, and the urine was full of blood. X ray examin tion for stone was negative.

On May 27th, under ether anæsthesia, cystoscopy show that the bladder mucous membrane was covered with lar purpuric patches between which the mucous membrane w healthy. Blood was pouring in cascades from the left urete A specimen obtained by catheter from the right kidney w natural and of good functional value. As the bleedin seemed grave and increasing in severity day by day, it w decided to remove the left kidney.

On opening the kidney after its removal it was found t contain a large number of purpuric spots and patch beneath the pelvic mucous membrane. No other pathologic changes could be found.

The patient was given three doses of 25 c.cm. of ant streptococcal serum by the mouth at intervals of 48 hour

* This case was described in my book, "Common Infectio of the Kidney," 1920, p. 287.

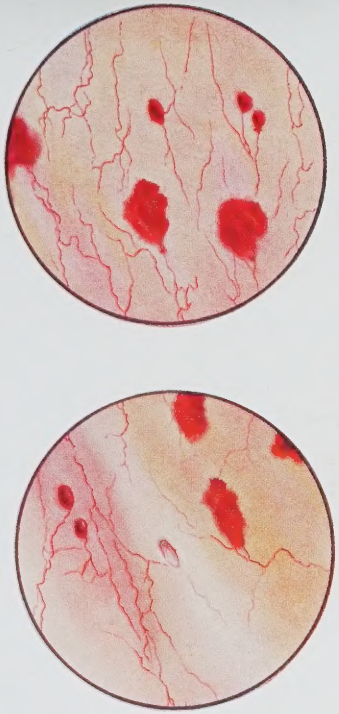

FIG. I.

FIG. II.

FIG. III.

Fig. I.—Cystoscopic appearance of purpura of the bladder showing petechiæ. The blood-vessels seen are veins, and the petechiæ are apparently formed by an exudation of blood-stained fluid or blood into the tissues around the capillaries just before they enter the finest veins. The edges of the petechiæ, though irregular in places, are sharply defined, and there is no inflammation around them. The larger patches sometimes appear very slightly raised, but the mucous membrane is usually intact. They vary from the size of a pin's head to areas ½ in. or more in diameter, and may be scattered over the bladder or confined to one small area. The rest of the mucous membrane is generally normal or at most shows very slight engorgement of the blood-vessels. Occasionally, however, there is mild diffuse submucous inflammation of the whole wall of the bladder, in the midst of which the petechiæ stand out plainly as blood red spots and patches.

Fig. II. (Case 4).—Kidney showing purpuric spots scattered throughout the pelvic mucous membrane, which appears pale and healthy between the petechiæ. Similar spots are evident between the collecting tubules in various places, but there is no generalised engorgement of the blood-vessels caused by inflammation.

Fig. III. (Case 5).—A large oozing submucous hæmorrhage is seen in the pelvis of the kidney.

covery was uneventful and the patient appeared to regain usual state of health.

There was no further trouble until October, 1925; then a week she had slight fever, and two attacks of slight maturia and increased frequency. She was given three es of antistreptococcal serum by the mouth. The eding at once stopped.

The teeth were X rayed and five or six dead stumps noted, removal was refused. The urine and fæces were mined by Dr. Alexander Fleming, who found a hæmolytic ptococcus in the stools and a strain of *B. coli* which the od agglutinated in high dilutions. Autogenous vaccines e started. *The first dose produced a severe attack of naturia.*

Oct. 19th, 1925. *Cystoscopy.*—The bladder was full of s, which had to be washed clear. Several large and many all purpuric patches could be seen on the base of bladder. e was abraded and bleeding. It was advised that she uld go on with vaccines but in smaller doses, take ium lactate from time to time, and have three doses of istreptococcal serum by the mouth if she were to bleed.

Jan. 28th, 1926. She has had the vaccine once a week ularly and the bleeding has stopped completely. Before vaccines were started coli agglutination of serum was 100; now it is 1/2500. No agglutination of streptococci. sonic index to streptococcus 1·34. Her general health greatly improved, she has no fever, and is able to get ut. If more than 0·5 c.cm. of vaccine is given she gets a ction in the bladder, accompanied by hæmaturia. She s again advised to have the teeth removed.

August 4th, 1926. She has been wonderfully well. Six d teeth have been extracted. There has been no norrhage since then, till this week. She is putting on ght and looks quite fit again. She has had 1/5th c.cm. vaccine regularly once a fortnight. Last week a drop of od on napkins. Cystoscopy revealed four or five tiny puric spots just at entrance to urethra on the trigone.

Feb. 24th, 1927. She has been the picture of health has had the vaccine regularly. During the last few s she has noticed a few drops of blood on her napkins slight pain in the urethra. The bladder appeared lthy except for a large purpuric patch on the trigone, at the entrance to the urethra. Three more doses of im given.

March 17th, 1928. She writes to say she considers that is completely cured, as she has had no more trouble and n good health.

Note.—This was the only case out of eight with purpuric neys where pain was felt. The remaining seven kidney puras had painless hæmaturia.

Purpura Simplex; Purpura of the Kidney.

CASE 4.—A married woman, aged 40, first examined in ember, 1923, had suffered for one week from profuse but nless hæmaturia. The urine contained blood, but no pus, was sterile. Cystoscopy showed that blood was pouring ascades out of the right ureter. The efflux from the left er was clear, and the left kidney was of good functional ue. A pyelogram of the right kidney showed a double vis, but no evidence of tumour. As the bleeding appeared be endangering life the right kidney was removed early January, 1924. Examination revealed no pathological nges, except the presence of a number of purpuric spots tered throughout the pelvic mucous membrane (Fig. II.). Recovery was uneventful. The tonsils, which were rged, were removed. Since then there has been no her trouble of any kind, and in 1928 the patient is known be in excellent health.

Purpura Fulminans; Purpura of the Kidney.

CASE 5.—A man, aged 59, was first examined on August 16th, 1. His doctor stated that in May, 1918, patient had suffered n pain in the abdomen and diarrhœa. In May, 1921, he a second attack accompanied by fever, and was in bed lays. On July 14th, 1921, he had pain in the pyloric end tomach and fever, and had to go to bed, where he had n ever since. On August 3rd, 1921, he had an attack etching and spat up blood, *which came from the teeth.* t day he started profuse hæmaturia, which persisted since, with no pain in bladder or kidneys, but with slight r all the time. The urine is said to contain *B. coli* on ure. It contains a large quantity of blood, a few helial and blood casts, but no pus. The temperature is er above 100° F. Calcium lactate, acid. sod. phosphate, later, alkalis and hamamelis, were given without eficial result.

n examination the patient looked weak and anæmic n loss of blood. The kidneys were not enlarged. Cysto- by showed the bladder wall not inflamed and blood ring out of right ureter. The urine from the left kidney clear and of good functional value. The gums were gy and blue, and blood was weeping slowly from the gins round the teeth. There was a large subcutaneous norrhage over the front of the right ankle. A provisional diagnosis of purpura was made, but as the pulse-rate varied between 70 and 90 per minute it was decided not to operate. The patient was flooded with alkalis and given hæmoplastin. The urine on cultivation yielded the *Streptococcus fæcalis* and a Gram-negative bacillus. Blood cultures were negative.

On the evening of August 17th the bleeding was more profuse and the patient was becoming blanched and restless, the pulse-rate having risen to 120 per minute. As it was obvious he was bleeding to death the right kidney was exposed. *The wall of the ureter was œdematous and glassy*, as is often seen from irritation by blood. The ureter and pelvis were distended with blood, but there were no clots. The right kidney was removed. On opening the kidney the cause of the hæmorrhage was apparent. The pelvis of the kidney was covered with purpuric spots, some the size of a pin's head, some of medium size, and there was one quite large submucous hæmorrhage in the middle of the pelvis. There were tiny white areas of fibrous tissue in the centre portions of the pyramids (see Fig. III.).

Dr. Elizabeth Lepper examined the kidney while fresh, mounted it, and furnished the following report:—

"The acute changes are almost limited to the mucous membrane covering the parietal wall of the pelvis; here the vessels are markedly dilated and full of polymorphonuclear leucocytes. There is a moderate round-cell infiltration of the submucous tissues and between the epithelial cells, and a very marked extravasation of red blood corpuscles, which accounts for the naked-eye appearances and presumably for the hæmaturia, though in consecutive sections I have not been able to demonstrate any actual loss of epithelium exposing a vessel. There is slight leucocytic infiltration at the tips of the pyramids. The changes in the cortex are chronic in character, some patches of fibrosis being present. There is, however, cloudy swelling of the epithelium of the tubules. No organisms have been found in any of the sections. Cultures made from the fresh specimen and from the urine grew the *Streptococcus fæcalis* and a bacillus of the proteus group."

Progress.—There was considerable shock for 24 hours, but next day the urine was clear of blood and the patient took a turn for the better. He was given hæmoplastin and alkalis.

August 21st, 1921. A bruise appeared on the left arm.

The wound healed on the ninth day, but continued to ooze a little blood-stained serum. Gastro-intestinal disturbances became more marked.

The patient went on fairly well until August 31st, 1921, and had no more hæmaturia. Then acute delirium, rigidity, and twitchings started suddenly. From this day on he got gradually worse. Though there was no return of any hæmorrhage, yet about the middle of September he gradually sank and died.

This case appears to represent a fulminating reaction to poisons absorbed from the teeth and alimentary canal.

SUMMARY OF THE TWENTY-FOUR CASES.

The condition affected females more often than males (19 to 5); the mild type usually attacked young children (6), and the more serious type those well advanced into middle age (18). Fourteen cases could be grouped as purpura simplex, 8 as purpura recurrens, and 2 as purpura fulminans. In 16 cases the purpura was confined to the bladder, in 3 cases it was present in both bladder and kidneys, in 5 cases it was confined to one of the kidneys.

Hæmaturia was present in all, was mild and transient in seven, was profuse and abundant, lasting for days at a time in ten cases, and was profuse, alarming, and dangerous to life in eight cases, so profuse that nephrectomy had to be carried out. In the two fulminating cases nephrectomy stopped the hæmaturia, but the patients died of exhaustion or of hæmorrhage elsewhere in the course of a few months. In the other six cases nephrectomy stopped the hæmaturia and the patients' lives were saved. Of these, three had no further trouble of any kind and are in good health, one had trouble for a time but is now cured, two still suffer at times from mild attacks of hæmaturia.

Pain was a marked feature in all the bladder cases, an intense strangury felt at the neck of the bladder, often so severe as to make the patient cry out, accompanied by distressing frequency of micturition. In all such cases petechiæ were seen in the bladder mucous membrane. Pain was not complained of in seven out of the eight cases diagnosed as renal. In this regard purpura of the kidney seems to differ from purpura of the bladder. In one renal case alone complaint was made of rather severe aching pain in the bleeding kidney, and in one other case the patient

noticed a sudden sharp stabbing pain in one kidney just as the hæmorrhage started, but it disappeared in a few moments and did not return.

Petechiæ and hæmorrhage occurred simultaneously in bladder and kidney in only three cases. In only two cases did it occur in the second kidney after the first had been removed for hæmorrhage. The bladder cases were far less severe than the kidney cases. In only one case was there evidence of a true nephritis, and in this case the condition was a large white kidney or "nephrosis."

The blood in the urine showed little tendency to clot, except in a child who had one attack of clot retention. Though there appears to be little if any delay in the clotting time in cases of purpura, yet there may be a diminution in the number of blood-platelets and a lack of firm retractile fibrin in the clotted blood, and the bleeding time is usually prolonged (Hayem, Duke, Frank). Exact observations of the blood were not made in a sufficient number of cases to make it possible to classify according to blood changes. No case of thrombocytopenia (Frank) was observed, but some may have been missed.

Fever was absent in 15 cases, and in the others was only very mild, the temperature seldom rising to more than 100° F., despite the grave condition of some of the patients. In this respect the cases differ markedly from ordinary cases of pyelitis and cystitis, and resemble and are sometimes mistaken for acute rheumatism if the joints are swollen. The cases described by Stevens and Peters appear to have been due to a peculiar type of poison related to the cause of trench nephritis.

Wasting was only noticeable in four cases and profound anæmia in eight. Many of the 15 ambulatory cases appeared remarkably well, despite the strangury and hæmaturia.

Eight patients were so desperately ill from loss of blood that nephrectomy was necessary. Only two other patients caused anxiety; in one recovery followed removal of an inflamed appendix and renal lavage quickly cured fever and pyelitis in the other.

The blood pressure was usually low, possibly due to loss of blood, a point which helps in the diagnosis from nephritis and congenital cystic kidney.

Two cases had intermittent painful swellings of the joints, seven had intermittent attacks of petechiæ or bruisings of the skin in various parts of the body, four had attacks of hæmorrhage from the bowel, and two had severe hæmorrhage from the gums. In these respects also they differed from the cases described by Stevens and Peters, wherein the lesions were confined to the bladder and kidneys.

Sources of Bacterial Infection.

As time went on it was recognised that the teeth and tonsils were most likely to be the cause of the trouble. In three children purpura of the bladder came on shortly after the enucleation of tonsils containing pure cultures of streptococci, but no pus could be detected in the urine. In another child the trouble came on the day after the extraction of a number of teeth infected with streptococci. In seven cases X ray examination of the teeth revealed septic stumps, the removal of which seemed to benefit the patients; in four streptococci were isolated in pure culture from the teeth and the urine. In eight cases the tonsils appeared diseased and were removed, and, in six of these, streptococci were isolated in pure culture from the tonsils and urine. There was usually a trace of albumin and an excess of epithelial cells in the centrifugalised urinary deposit. A few blood and epithelial casts might be present, but granular casts in large numbers were absent except in one case that had chronic nephritis. In nine cases the urine was sterile, and in the majority of cases no pus was detected in it. In this respect, again, the cases differ from ordinary cystitis and pyelitis. Bacilli of the colon group were isolated in eight cases, usually without pyuria. In nine cases it was possible to isolate cultures of a streptococcus from the urine in the absence of pus, in two associated with bacilli of the colon gro

THE EXPERIMENTAL BASIS OF RADIUM THERAPY IN CANCER.

By PROF. S. RUSS, D.Sc. LOND.,
PHYSICIST TO THE MIDDLESEX HOSPITAL.

Two years after the discovery of radium in 1898 was already being used for the treatment of perficial malignant growths and its employment as gradually extended to the treatment of nearly very variety of malignant disease. The rays from dium and other radio-active bodies are now niversally looked upon as definite therapeutic agents r cancer. Since 1910 there has been no need for ncertainty about the measurement of radium, for that year, international standards were adopted. t the present time, if careful and detailed descrip-ons of any particular radium technique are recorded, e same treatment, with identical dosage, can be llowed by others in any part of the world. The me dose can be given again and again in exactly e same form. When we remember the great fficulty of exact measurement of dosage when using ray bulbs of varying output, this great advantage radium is evident. Generally, the dose is expressed the quantity of radium used and the length of posure; it is essential to add a description of the plicators or tubes, and to state exactly their sition. Only when this is done can any comparison made of the doses received at different points in e tissues.

Selective Action of Radium on the Tissues.

The effect of radium is not the same on all tissues, d the full effect of a dose of its rays is often delayed several weeks. One of the first facts known from periments was that when a malignant growth was ven an effective dose of rays the cells gradually olved and were not killed at once. There is no vious sudden destruction of malignant cells, but her a series of changes which, after stopping ision and growth, ultimately causes the disappear-ce of the cells. Time is an essential factor in this ies of events.

If a mouse or rat tumour is given a lethal dose of mma rays and some of it is transplanted into other rat or mouse, as the case may be, tumour ls can be found alive and practically indistinguish-e from the normal tumour cells for about 6–7 days; this time some degenerate changes are recognisable. The rays have essentially a selective action. They ve much more destructive effect on lymphocytes some glandular structures, such as the cells of the roductive organs, than on many other normal cells structures of the body; apparently, some of the st sensitive are muscle, cartilage, and nerve cells. The question whether the rays have a greater tructive action on malignant tissues than on the mal tissues of the host can hardly be answered a plain yes or no. No doubt, in time, we shall e accurate data which will make it possible to ce the different normal tissues of the body and ignant tumours in the right order of vulnerability, when this is possible on a quantitative basis, question may be answered more certainly than an now. But such a list of tissues, in the order of r vulnerability, is an exceedingly difficult thing nake; this is not due so much to the difficulties of ervation and experiment as to the fact that the tions of different tissues seem to depend on and y with the time and intensity factors of the dose. fact, it may be said that, granted the reality of ctive action, advantage can only be taken of it n the best conditions of dosage have been dis-ered for each tissue. Experimentally, it is not cult to find a physical dose which will have a al action upon animal malignant cells, but this sical dose can be arrived at in a very large number ays by variations in time and quantity and yet remain a lethal dose. Which of these ways is best to adopt when a malignant growth has to reated in situ is not yet definitely known.

The Optimal Dosage.

If a tube made of platinum, 0·5 mm. in thickness and 25 mm. long, containing 25 mg. radium element is put into a rapidly growing tumour in a rat for 48 hours, it can be shown that cells a little further than a centimetre away from the middle of the tube have had a lethal dose; for they will not grow when reinoculated into susceptible rats. Now this result can be equally well obtained by using 50 mg. of element for one day, or 5 mg. for ten days, the physical dose being the same in all three cases. The question is, which is the best kind of dose to use therapeutically. The reply can only be got by trial. Careful clinical investigations pursued to this end have brought us very much nearer to the time when optimal doses can be prescribed. It is important to know what are the lowest useful intensities; if 2 mg. of radium element per centimetre length of platinum tube are as useful as 20 mg., provided the time of exposure is adjusted accordingly, how much further down the scale of quantity is it safe to go? Experiment shows unmistakably that one cannot use very small intensities of radium and hope to get a lethal effect on malignant cells, for it appears that, just as with drugs or with electrical, mechanical, or chemical irritants, tissues normal or malignant can withstand these very small intensities more or less indefinitely, if a certain definite intensity of action is not exceeded. The tissues of the body are not altogether strange to ionising radiation, for it is credibly estimated that the penetrating cosmic radiation creates about a million ions per second per individual struck. The limiting intensity for any deterrent action obviously sets a limit to the useful range of radium tubes. Beyond the lethal range of a tube there is a range within which there is definite evidence that growth is hindered, and beyond this, a region in which the cells, though irradiated, are able to cope with the irradiation, even though it is prolonged more or less indefinitely.

This important fact sets a definite limit to the range of effect of any radium applicator or tube. This range is rarely as much as an inch through tissues. In treating cases of cancer with radium, unless we can visualise the range of effect with some accuracy, tracts of growth are apt to be left untreated; this is a vital point, and it emphasises the necessity of carefully planning the radiation, so that the whole of the involved region receives an effective dose. The radium should be distributed in as many foci as practicable, rather than concentrated in one spot; for too intense local irradiation, with the outlying parts not adequately treated, tends to cause unnecessary local damage.

Stimulation of Growth and Acquired Immunity.

The question is often raised whether weak irradiations can stimulate tumour growth. A good deal of experimental work has been done on this subject, and there has been some conflict of opinion upon it; this is probably due to the fact that, if cells do grow more quickly under weak doses of gamma rays, they certainly do not grow much more quickly, and there may well be differences of opinion over small differences in rates of growth. And yet it is, I believe, an experience sometimes met by clinicians that, after radium has been put into a septic malignant growth, the growth continues at an apparently greater rate; it seems safer to attribute this rather to the sepsis and necrosis than to a direct action of weak doses upon the proliferating power of the cell. There is, of course, the disquieting possibility that quiescent cells may be brought into activity by weak doses of gamma rays, but at present we have no definite experimental evidence on the point.

Some very early experimental studies showed that some varieties of cells appeared to be more affected by a dose of rays if they were actually undergoing division at the time than if they were in the resting stage. Normally, of course, only a small percentage of the cells in a tumour is in a state of division at any particular moment, but there is a distinct chance

that by increasing the time of exposure a bigger number of dividing cells can be irradiated. Exposures lasting a week or more are now often used, and in some cases it is maintained that better results are got in this way, but it would be risky to conclude that this was due to the irradiation of a bigger percentage of dividing cells, for it may just as likely be due to the fact that growing cells are more affected by long-continued weak intensities than by short, strong ones.

It has been proved, clinically and experimentally, that malignant growths given repeated, sub-lethal doses of gamma rays often develop an increased resistance to the action of the rays. In fact, tumour cells, after repeated irradiation, have been found to withstand as much as 2½ times the normal lethal dose. This means that any form of radiation treatment should be planned so that the whole dose of radiation is given within a reasonable time and not repeated indefinitely. The fact that normal tissues are profoundly affected by gamma rays brings with it the practical certainty that the effect which a dose of these rays has on a malignant growth in the body is to some extent dependent on what the rays do to the normal structures around. In fact, we have experimental evidence that malignant cells do not grow so readily into regions of the body which have been irradiated. Naturally this effect is dependent upon the dose given, and much more work is needed before definite data can be given.

Malignant growths adequately irradiated may disappear locally, but there is very little evidence that in so doing the tumour cells which are absorbed have any deterrent action upon metastases. And yet there is the experimental fact that, when mice or rats which are ordinarily susceptible to tumour implantations have been inoculated with tumour which has had a lethal dose of radiation, a subsequent implantation of the normal tumour does not grow, and such inoculations can be made repeatedly on the same animal with a negative result. A closer parallel to the human case is, however, provided by spontaneous tumours in these animals, and up to the present it has not been shown possible to influence the formation of metastases in mice or rats by the irradiation of their primary spontaneous tumours. Very little work has been done on these lines owing to the difficulty of obtaining satisfactory conditions. Some evidence, however, exists to show that under certain conditions substances may be extracted from an irradiated tumour which actually stimulate tumour growth, and in this rather disturbing possibility some of the bad results of radium therapy may find an explanation.

Mode of Action.

As radium is used so much in the treatment of cancer, it is natural to want to know if an answer can be given to the question, How does it act? The outstanding fact of selective action does not in itself give any immediate clue to the answer to this question, just as the specific action of a drug on some particular organ of the body may still leave us ignorant of the way in which it acts. The most striking physical effect of gamma rays is that, when they pass through any medium, whether it be air or water, or the tissues of the body, they liberate negative electricity throughout the medium—i.e., they ionise it.

In certain cases it is very easy to measure this liberation of electricity and, in fact, the measurement of ionisation currents in air is the basis for all the standard physical measurements of gamma ray activity. In the tissues of the body it would be difficult to make such measurements with any accuracy because, normally, the electrolytes present give far bigger currents than those which would be produced by therapeutic doses of gamma rays. Yet this action is in all probability the one which, when intensity is great enough, at any rate starts processes which lead eventually to the damage of cells. One of the first steps in any attempt to explain how the rays cause these reactions in the tissues seems to consist in finding out how much local differences in ionisatio can upset cell equilibrium.

In this connexion there appear to be two ver significant facts; one is that under normal conditio the pH of the tissues is a very constant quantity, th other is that the ionisation produced by gamm rays in going through a medium is not a perfectl uniform process, for at any instant some regio are being ionised and others not. It has bee estimated that when a beam of gamma rays goe through the air it only ionises about one molecu in a million of those through which it passes, an probably the same sort of thing occurs in the tissue A locally intense ionisation is a process to which th tissues are ordinarily quite unaccustomed, an consequently they may find considerable difficult in accommodating themselves to it.

VARICOSE ULCERS:

A COMPARISON OF TREATMENT BY ULTRA-VIOLE LIGHT AND UNNA'S PASTE DRESSINGS.*

BY DORA C. COLEBROOK, M.D. LOND.

THE object of this inquiry was to observe the effe of irradiation by mercury-vapour arcs on the co dition and course of healing of varicose ulcers. Th subject appears to be a suitable one because (*a*) progre in the condition is measurable by simple means (*b*) it is commonly reported that irradiation in th condition is associated with certain definite effect (1) a direct or indirect bactericidal effect; (2) a effect on the vessels of the ulcer or on the circulatio of the whole leg; and (3) a stimulating effect o epithelial growth. It is claimed that the chang resulting from the action of the light in these thr respects on the character of the ulcer and its di charges are readily appreciated by the naked eye.

The number of ulcers was 84 (68 patients); 37 we treated with light and 47 with Unna's paste. Eleve ulcers are omitted from the tables (6 light and 5 Unn cases, all of which healed rapidly) because they we so small or so recently under treatment that the gave no clear evidence of the extent to which th special treatment had contributed to the resul Three Unna cases (5A2, 25A1, 61A), all of which di badly, are also omitted from Table A because, owin to various difficulties, they were dressed witho regard for the three principles suggested in this pap as essential. Of these three cases, two (5A, 25A) hav recently made striking progress with a new trial the paste dressing; one (61A) has not reappeared.

The Wassermann test was made in every ca where the appearance was at all suggestive of syphilitic infection. One case only (58A) giving positive reaction was included in the series becau it had already withstood antisyphilitic treatmen and appeared to contain a varicose element. Apa from this case, all the ulcers gave the history an showed the appearance and distribution associate with varicose ulcers.

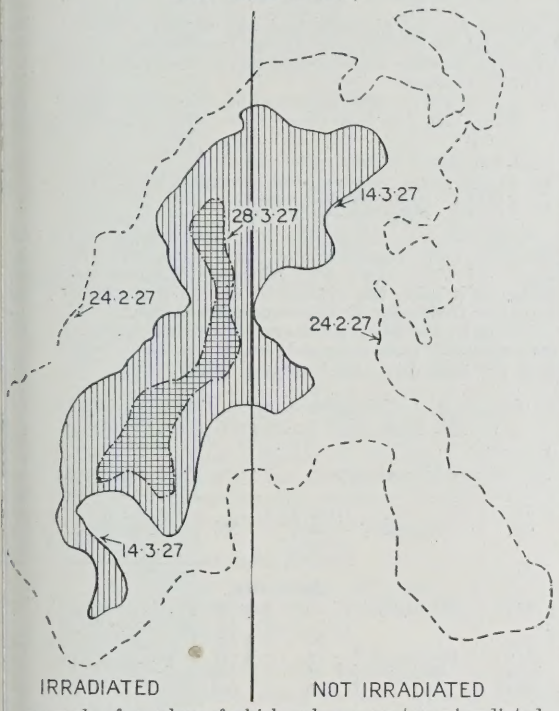
Evidence of Progress.

The attempt was made throughout to depend o objective rather than subjective evidence, an although notes were made of the observed state the healing edge, of the base of the ulcer, and of th discharge, as well as of any striking alteration the patient's symptoms, chief reliance was alwa placed on the actual surface measurement of th ulcer, and on the subsequent behaviour of the sca Further, in the light cases no support other than th which the patient was in the habit of wearing, an in the Unna cases no antiseptic or application oth than a simple zinc preparation was used. Whe

* This paper forms part of a report to the Medical Resear Council. A table giving full details of the cases and th treatment will be supplied by the author to anyone who interested. The case-numbers (in brackets) in the text ref to this table. (Table C.)

r any reason, an exception to this rule was made, note to that effect is found in the tables. At tervals of 14 to 21 days the edge of the ulcer was aced on transparent cellophane tissue with a fine ush and the line subsequently pricked out on to

FIG. 1 (Case 15 A).



n example of an ulcer of which only one part was irradiated.

per for a permanent record. The series of superposed tracings in different coloured inks gave a ry clear picture of progress so far as size was ncerned. (See Figs. 1 and 2.)

Methods Used.

A. *Light Cases.*—The burners used were: (1) Two e-cooled Hanovias of vacuum type for A.C.;) one air-cooled K.B.B. of atmospheric type for C.; (3) one water-cooled Hanovia (Kromayer) for C.; (4) one water-cooled K.B.B. for D.C.

Dosage.—Irradiation was in every case local, but the whole the leg up to the knee was exposed except in those cases which a very strong dose was given. It is not suggested at a general systemic effect could be excluded. For the ke of brevity, and because figures relating to time of posure and distance of patient from lamp are only useful ere there is a standard output from the lamp, the doses th the air-cooled lamps are given in terms of a roughly imated erythema, produced on similar areas of the skin an individual of about average sensibility. It was found this test that the air-cooled burners gave an erythema ting for at least two to three days, at a distance of eet, in four to seven minutes according to the age of the rner, while the water-cooled lamps applied to the skin ve a marked reaction with multiple small blisters in to 50 seconds. Since neither the ulcerated surface nor the ghly pigmented region surrounding the ulcer showed any ythema, the term is merely used as a comparative one, t where an actual definite reaction was seen on the althy skin beyond the pigmented area, the fact is indicated Table C. The doses given with the water-cooled lamps e expressed in minutes. The mild doses were given with e air-cooled lamps at 2 feet, the stronger doses with the -cooled lamps at 1 foot or with the water-cooled lamps in ntact. Where a strong dose was given to the ulcer the in immediately surrounding it was protected.

Treatment was usually given twice or thrice weekly, but ere a strong dose was given a longer interval was some- nes left.

All the bed patients, many of the ambulant patients, d all those exposed to the water-cooled lamp were treated the writer personally; a certain number of the ambulant ses were treated by the nurse-in-charge under direction. It was the rule for all except the more chronic cases to be seen by the writer at least once a week.

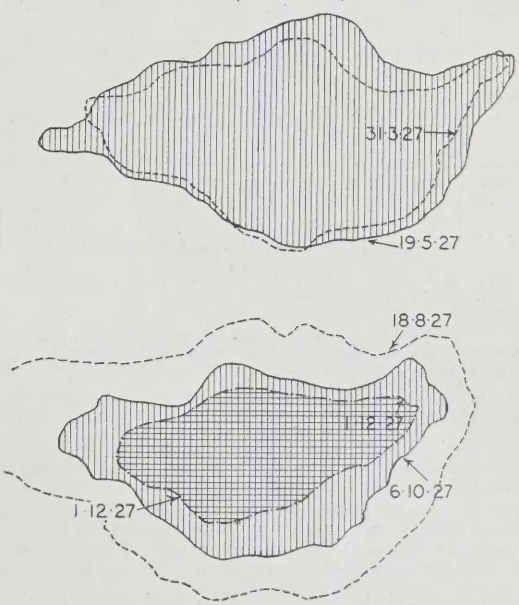
Dressings.—Normal saline and liquid paraffin were used as dressings on account of their ability to transmit the shorter rays. A spectroscopic test of the paraffin showed that wave-lengths down to 2400 A.U. passed through a layer 1 mm. or less thick with practically no absorption. For bed cases no other dressings were used, but when ambulant patients were intolerant of them, they were replaced by simple ointments which were wiped off before treatment. Although it was obviously impossible to cleanse the surface completely without damaging the granulations, no retardation was noted with the change over to this type of dressing.

B. *Unna Cases.*—The composition of the paste used was: zinc oxide 6, gelatin 4, glycerine 12, and water 16 parts by weight. Two and a half inch bandages of thin white muslin without "dressing" were used. They were soaked in water and wrung out as dry as possible before application. The paste was melted on a water-bath and used as hot as could be tolerated quite comfortably.

Three conditions were thought to be essential: (*a*) that the half foot, the heel, and the whole leg as far as the knee should be evenly covered; (*b*) that the bandage should be pasted on without pressure in any direction; and (*c*) that during change of dressings the leg should be kept in the horizontal position.

The actual method of bandaging varied according to the case; where the leg was slim, the foot and ankle and the lower quarter of the leg were completed in the first stage, the rest in the second. Where the leg was very shapely or showed prominent veins, strips were applied, each starting round the foot or ankle and sweeping up in a one- or two-turn spiral to the knee; thus successive areas were covered and an upward pull exerted. Each layer of bandage was

FIG. 2 (Case 26 A).



The upper diagram shows the change in outline of a varicose ulcer (Case 26A) between March 31st and May 5th under treatment by ultra-violet light. The lower shows the improvement after readmission on August 18th when treatment with Unna's paste was begun.

covered with a layer of paste. In the great majority of cases the bandage and paste were applied direct to the ulcer; in a few cases the ulcer was first covered with a simple zinc ointment and some layers of gauze. In many cases a rubber sponge [1] was inserted between the first layers of the bandage. The sponges were 1¼ inches thick and cut to a size a little larger than the ulcer.

The dressings were usually changed twice weekly for at least the first two or three times; if pain was relieved and the aspect of the ulcer was reassuring, the interval was gradually prolonged to 7, 14, or 21 days. Except in the first case of the series (2A), windows for dressings were not left. Experience of three cases (26A, 27A, 65A), in which the

[1] See G. Nobl: Wien. Med. Woch., 1925, lxxv., 1981.

skin surrounding the ulcer became sodden and showed denuded areas, led to the exercise of great caution when any redness occurred under the bandage.[2] On the other hand, it was frequently found that even where the ulcer was large the dressing could safely be left on for seven days, and, although it was very foul when taken off, the aspect of the ulcer was most satisfactory.

Pm. = perimeter.

Groups of Cases Treated, with Results.

The cases may be divided into five groups according to the treatment employed. In *Group A* the ulcers were treated with ultra-violet light, in *Group B* with Unna's paste. *Group C* consists of cases which failed to respond to light and were dressed with Unna's paste. The patients in *Group D* had two or more ulcers and in each case one of these was irradiated. Lastly *Group E* comprises ten cases in which the ulcers were so large that a part of them could be irradiated while the rest was otherwise treated.

Group A.—31 ulcers (15 bed, 16 ambulant cases) were treated with ultra-violet light. Further reference to 14 of these is made in Group C. (For results, see Table A.)

TABLE A.—*Summary of Results.*

Cases.	Healed.		Improved but not healed.		Unchanged.		Worse.		Total.	
	Light.	Unna.	Light.	Unna.	Light.	Unna.	Light.	Unna.	Light.	Unna.

Figures in parentheses are percentages.
* 8 made no progress during last weeks of treatment.
4 made so little progress that other treatment was subsequently used.
3 discharged themselves when the ulcer was not quite healed.
† 10 are all making good progress, treatment continuing.

(1) Bed cases: 2 (18B Pt, 12B Pt) healed. In both cases a non-irradiated portion of the ulcer healed at the same rate. (2) Ambulant cases: None healed.

Group B.—39 ulcers (9 bed, 30 ambulant cases) were treated with Unna's paste. Further reference to 14 of these is made in Group C. Of the remainder, 7 had previously attended the hospital for varying periods but had made no progress. (For results, see Table A.)

(1) Bed cases: 4 healed. (2) Ambulant cases: 23 (including the 7 mentioned above) healed.

In the attempt to judge the part played by the light in this condition, in which spontaneous variations occur and on which many influences are at work, comparison was made, not only with the cases treated with Unna's paste as a whole (see Groups A and B), but also with cases treated first with light and later with Unna's paste (see Group C), and with certain untreated ulcers or parts of ulcers in the same patients as the treated areas and dressed with the same dressings (see Groups D and E).

Group C.—14 ulcers which had failed to respond to light were dressed with Unna's paste. (See Table B.) Of the 9 ambulant cases 6 healed, and the remaining 3, which are still under treatment, have shown marked improvement.

[2] The use of "blue paint" (crystal violet and brilliant green, ½ per cent. of each in rectified spirit and water) to the surrounding areas, as suggested by Dr. H. Haldin-Davis, is now being tried.

Group D.—4 patients had more than one ulcer. All h the same dressings; one ulcer in each case was irradiat
(1) Bed case: (12A and 12C). Same rate of healing in bo
(2) Ambulant cases:
1 (33 A and B). No improvement in either.
1 (62 A and B). No change in irradiated; deterioration non-irradiated ulcer.
1 (54 A, B, and C). Deterioration in all three areas.

Group E.—10 patients had ulcers (11) sufficiently la for a part to be screened during irradiation; in 4 of th a small area only was exposed to the water-cooled lamp.
(1) Bed cases:
2 (18A, 52A). More rapid healing in screened parts.
5 (8A, 12B, 15A, 18B, 32A). Same rate of healing in b parts.
(2) Ambulant cases:
2 (10A, 25A). Same rate of healing in both.
1 (19A). No progress in either.
1 (34A). Deterioration in both.

Inferences to be Drawn from the Above Groups.—(1) Amb lant cases: The superiority of Unna's method is very clea seen. (2) Bed cases: The difference is much less mark So far as it goes, the evidence suggests that the rest rat than the treatment is the important factor.

Owing to the small numbers no conclusions can be dra with certainty from Groups D and E, but there is no evide that the light has any beneficial effect.

TABLE B.—*Comparison of 14 Cases Treated First with Light and Later with Unna's Paste.*

* Treatment continuing.
† Developed new ulcer, treatment abandoned.
‡ Has since healed as an ambulant case.

Effects of Varying Doses of Light.

1. Suberythema doses were given in the early stages treatment to 30 ulcers, and in 10 nothing further was tr over a period of several months. These cases on the wh ran a more favourable course than those having stron doses. The significance of this observation is discus later.

2. Erythema doses with the air-cooled lamps were gi to 20 ulcers; of these 8 showed a good reaction on whole leg. In many cases the ulcer only was expos While there was temporary improvement in a few cases, others no effect or a deterioration was seen.

3. Erythema doses with the water-cooled lamps w given, to the ulcer only, in 6 cases. In these cases, exposu of 4, 5, or 7 minutes were reached before the method abandoned. In none of these, apart from a dryness of surface immediately after exposure, was there any appar change in the condition of the ulcer. Four (8A, 10A, 1 34A) showed no alteration in size; two (23A, 25A) mad little progress, but both ulcers had previously improved about the same rate when under suberythema doses w the air-cooled lamps. Four (8A, 10A, 25A, 34A) had lamp applied to one part only; these parts showed distinctive changes.

Number of Doses Given.

—	Max.	Min.	Aver
Suberythema	40	4	15·5
Erythema (air-cooled lamp) ..	30	2	10·0
Erythema (water-cooled lamp)	23	5	11·5

Five patients only had less than 12 doses, three because he ulcer had not improved or was worse, two because the lcer was nearly healed and the patients wished for their ischarge.

Conclusions as to Dosage.

1. Progress was chiefly associated with the periods of ild irradiation. For this reason a very extended ial was given to this method. It must be borne mind, however, that the circumstances in which e mild doses were used—that is, in the early stages f treatment—were exactly those in which other eneficial influences are especially operative—viz., the bed cases the influence of the rest itself—an fluence most apparent in the earlier weeks of cumbency, and in all cases the influence of a change f treatment, of extra cleanliness, and of careful ressings. Moreover, since in this group the average eriod of irradiation was longer, the chances of ontaneous recovery were greater. The suggestion at the rôle played by the light itself was an important one is supported by the following bservations: (*a*) where comparison was made in is series, the behaviour of irradiated and non-radiated areas or ulcers was similar; (*b*) in many ses progress was not maintained, relapses occurred, d a continuation or a further course of similar eatment to the relapsed area was ineffective. Where a case was making little or no progress onger doses did not appear to accelerate healing. Where fluctuations in condition were noted they d not appear to be related to dosage. 4. Periods of st from treatment gave no indication of value.

Harmful Effects.

Although a certain percentage of cases did badly, ere was nothing in their behaviour to suggest that e irradiation actually did harm.

Progress of Unna Cases.

Whereas, in the light cases it was difficult to see y relation between the routine and the result, perience with Unna's paste strongly suggests that ilure may be associated with faulty technique. eference to this point has already been made in nnexion with excluded cases. No attempt has been ade to determine to what extent the rubber sponges ve contributed to the results; it is certain, however, at in a number of cases a most definite advance healing and in comfort followed their use.

Behaviour of the Scar.

The two (bed cases) patients treated by light, parts whose ulcers healed, have not been traced. It was not anticipated that the scar resulting from e use of Unna's dressing would provide any ception to the usual history of relapse; patients re, therefore, urged to attend for monthly applica-ns after healing had taken place. Most of the na cases were treated in the late summer of 1927, that they have been under observation since aling took place for three to four months only. 15 patients who have reported recently, 12 have en wearing the paste for at least three months; ne has relapsed, and all are absolutely comfortable. the three who left off the dressing, two had relapsed thin four months.

Other Evidence of Progress.

Although chief reliance was placed on objective dence of progress—namely, on measurement—it is ly recognised that a statement of size alone gives a y incomplete picture of the condition of an ulcer. ile no alteration in size may be demonstrable over ertain period, the most striking and incontrovertible anges may be apparent in its depth, the steepness its edges, and the character of the granulations. hen these changes are favourable, it is reasonable assume that they will be followed eventually by satisfactory rate of healing. Generally speaking, n where there was a decrease in size, irradiation s not associated with a healthy aspect of the ges and base. In the Unna cases, on the other hand, particularly when a rubber sponge was used, it was usual for the surface of the ulcer very quickly to undergo a striking change, to show flat edges and fresh red granulations. When allowance is made for the spontaneous variations in the condition of the ulcer which occur from time to time, it cannot be said that any appreciable relief of subjective symptoms was obtained from light treatment. The Unna dressing was associated with rapid disappearance of general discomfort and the feeling of heaviness and "inflammation" in the leg; the pain in the ulcer was in many, but not in all cases, as easily relieved. The occurrence or recurrence of pain was found to be a useful indication that all was not well; very notable comfort after the first week or two usually coincided with actual healing.

General Conclusions.

1. *Rate of healing.*—The effect of the light was markedly inferior to that of the Unna's paste, the most striking difference showing in the ambulant patients, many of whose ulcers had previously healed only with rest in bed. (For figures, see Table B.)

2. Favourable *changes in general character*, which were slight or absent in the irradiated ulcers, occurred at an early stage in those dressed with Unna's paste.

3. *Relief of symptoms* was not obtained during light treatment, but was a marked feature of the Unna cases.

4. The use of rubber sponge compression on the ulcer appeared to be definitely advantageous.

It is not claimed for this inquiry that it was an exhaustive examination of all possible methods of irradiating varicose ulcers. It was, however, hoped that a sufficiently extended trial, in carefully selected cases, of dosage ranging from very mild to very strong might serve to give some definite indication of effect and of practical utility.

The incidence of the disease falls on workers, and especially on men and women whose occupation involves much standing; the method of choice, therefore, must be that which involves the minimum attendance for treatment. It was the urgency of this aspect of the question which first led to a consideration of the claims made for the method of Unna as an alternative, and not merely as an adjuvant to any other, and hence as a control to treatment by ultra-violet light.

I acknowledge with much gratitude the facilities given me for this study—with the kind consent of the Boards concerned—by Dr. Haldin-Davis and Dr. C. B. Heald, of the Royal Free Hospital; by Dr. Remington Hobbs, of St. Mary Abbot's Hospital; and by Dr. Arthur Reade, of New End Hospital; as well as the coöperation of sisters and nurses in these institutions, and particularly of Nurse Cresswell, of the Royal Free Hospital, who has so ably and enthusiastically assisted me in the work. I am much indebted to Dr. Edgar Schuster and to Miss E. M. Newbold, M.Sc., for help with tracings and figures respectively, and to Dr. R. B. Bourdillon for criticisms and suggestions.

MANCHESTER AND DISTRICT RADIUM INSTITUTE.—The annual report for 1927 states that this institute was the first fully equipped hospital in the United Kingdom for treatment by radio-active substances. There are 14 beds for in-patients, two of them being set aside for paying patients. The existing stock of radium is quite insufficient, and the period of waiting for treatment sometimes removes all prospects of relief. The in-patients treated during the year numbered 566, and the total attendance of out-patients was 6976.

A HOSPITAL AT £600 PER BED.—The Park Poor-law Hospital at Davyhulme, which is being built by the Barton-upon-Irwell Board of Guardians, is approaching completion. It will cost over £300,000, and its 500 beds will thus have been provided at the rate of about £600 each, which the guardians believe to be the lowest rate of any hospital in England. The buildings include all the necessary departments.

A NOTE ON THE USE OF BENZYL CINNAMIC ESTER IN TUBERCULOSIS.

THE METHOD OF JACOBSON.

By H. GAINSBOROUGH, M.B. Camb., M.R.C.P. Lond.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL.

In his thesis in 1919, Jacobson [1] established an analogy between tuberculosis and the diseases due to pathogenic fungi. In order to attack this infection he considered the possibility of using balsam of Peru, on account of its antiparasitic properties. Benzyl cinnamic ester is one of the constituents of cinnamein, the active principle of balsam of Peru. We know as a result of Jacobson's researches on the biological properties of the two radicles, the cinnamic and the benzyl, which together constitute benzyl cinnamic ester, that the cinnamic radicle hinders the growth in culture of the bacillus of Koch, diminishes the febrile reaction which occurs in a guinea-pig after the injection of tuberculin, and also produces an appreciable leucocytosis after its administration subcutaneously. The cinnamic radicle, in the form of sodium cinnamate (hétol) or of cinnamic acid which were studied by Landerer, has not these properties except that when injected intravenously a leucocytosis is produced. The benzyl radicle, studied by Jacobson [2 3 4] in the form of benzyl alcohol, has a powerful dissolving action on the tubercle bacilli in vitro. These bacilli, mixed with benzyl alcohol, and injected into guinea-pigs do not produce visceral tuberculosis or even cold abscesses; lethal doses of crude tuberculin mixed with this alcohol and injected into guinea-pigs do not cause death.

French Experience.

Clinically, benzyl cinnamic ester has given some encouraging results in the treatment of pulmonary tuberculosis; but in order to observe more closely the effect of this compound on the lesions of tuberculosis Jacobson first of all treated forms of tuberculosis which were external and visible and consequently more easily observed, particularly lupus.

The results which Jacobson [5] obtained in the treatment of tuberculosis of the skin at the Hospital St. Louis have been confirmed by Darier,[11] Jeanselme,[12] Mitchitch,[14] Froissard,[17] and by different observers at the three Congresses of Dermatology—Paris 1922, Strasbourg 1923, Brussels 1926, and particularly by Vigne and Fournier.[20] Benzyl cinnamic ester has been shown to be equally useful in the treatment of tuberculous glands. Jacobson's results [9] in this respect have been confirmed by Sebileau [16] and by Desplas.[19] Especially suggestive results have been obtained in the treatment of genito-urinary tuberculosis by Cathelin and Brulé,[15] and by Tissot and Chaignon.[18] The preparation is no less efficacious in the treatment of tuberculosis of the mucous membranes. Jacobson [6] has reported his results in buccal tuberculosis confirmed by Jeanselme; Dufourmentel and Sebileau [16] and Caboche [21] for laryngeal tuberculosis.

As a result of the use of benzyl cinnamic ester these reports have demonstrated improvements in the actual tuberculous lesions, but apart from these the improvement of the patients has been definite, and in some cases very considerable. These results were so encouraging that Jacobson then tried the treatment of pulmonary tuberculosis, and in a recent communication [10] has reported the results on ten cases. The importance of this communication is not only in the improvement of the symptoms but the evidence afforded of rapid modifications in the diseased lungs shown by X ray examination and which makes this report particularly interesting.

After having learnt of Jacobson's researches I have myself endeavoured to observe the effects of the product in tuberculosis and have studied the action of Jacobson's solution at first on cases of extern tuberculosis which were more easily observed.

The results which I have obtained in a short tim appear to be sufficiently suggestive to be wort reporting.

Technique.

The treatment consists of a course of 12 dail intramuscular injections, followed by a rest of 1 to 18 days, after which the course is repeated twic in this manner so that three such series of injectio are given. The patient is then given one to tw months rest before restarting treatment in the sam manner.

The dose varies from 0·25 to 1·0 c.cm. of th solution, the former dose for pulmonary or bucc laryngeal cases, the latter dose for cases of extern tuberculosis uncomplicated by either former cond tions. There is no reaction, general, local, or foc after administration of this product.

Three Typical Cases.

The following three cases are typical of the resul obtained in all the cases so far treated.

Case 1.—D. K., male, aged 23. Tuberculous glands neck. General condition poor. Nov. 27th, 1927: In le anterior triangle of neck there is a mass firmly adherent skin and deeper structures discharging freely from a sin at the lower pole. Above it is a healed sinus. On the rig is a large freely movable mass of glands in the anteri triangle. This mass has only been noticed two or thr weeks; the other mass has been present for four month having been incised previously and then closed. Th wound broke down shortly afterwards. There is an evenin temperature reaching 99·5° F.

Treatment with benzyl cinnamic ester commence After the first series of injections the mass on the left si had disappeared, and the sinus discharge was very muc less. The mass on the right side had become larger ar fluctuant—the pyrexia had increased and there was son mental disturbance. He then left my care for a time b returned Jan. 4th, 1928. Treatment was restarted. Ear during the second course the right side started dischargi pus, and the swelling subsided. The patient's gener condition started to improve, he became afebrile, th discharge ceased on the left side, and shortly afterwar ceased on the right side. By the end of the third series injections, Feb. 16th, he had gained 8 lb. in weight, th left side appeared firmly healed, and the right side ha been dry for some days. There was no swelling on eith side of the neck, and he was quite afebrile. His appeti had improved enormously, his mental condition was norma and in general he felt much better.

Result: Very marked general and local improvement.

Case 2.—E. D., male, aged 29. Tuberculosis of kidne with cystitis. General condition poor. Patient pale ar anæmic; he had been suffering for over two years, bot kidneys were affected, tubercle bacilli had been found the urine, there were occasional attacks of hæmaturia. H had been treated with tuberculin B.E. On the whole h seemed definitely to be losing ground.

Dec. 5th, 1927: Frequency now $\frac{D\ \frac{3}{4}\text{ hourly}}{N\ 1\frac{1}{2}\text{ to }2\text{ hourly}}$. P complains of severe pain over the bladder, particular in the morning.

Treatment with benzyl cinnamic ester commence After the first series of injections the pain became definite easier; he gained 2 lb. in weight, and his general conditio improved as regards appetite and strength. The frequenc remained unchanged. During the second course of injectio he gained a further 2 lb. in weight, the pain practical disappeared, but an attack of hæmaturia occurred whic caused rather a set-back. After the third course, he regaine the weight he had lost, pain was completely absent, h general condition improved still further, and the frequenc was now $\frac{D\ 1\text{ to }1\frac{1}{4}\text{ hourly}}{N\ 2\frac{1}{2}\text{ to }3\frac{1}{2}\text{ hourly}}$. Patient feels quite certain his improvement. Total gain in weight 4 lb.

Result: Improvement.

Case 3.—S. W., male, aged 40. Tuberculosis of lun and larynx. Patient well nourished, but feels very wea and tired. History of cough for five months. Tuberc bacilli had been found in the sputum. He had been gettin increasingly hoarse for six weeks, this symptom havin appeared while he was in a sanatorium. He is dyspnœi There is considerable discomfort on swallowing and som pricking pains in the throat. Physical signs: Dullness the upper right lobe with almost tubular breathing at th apex. Hard crepitation at both apices. X rays sho extensive long-standing tuberculosis of the right upper lob

ad the left apex is not quite clear. Laryngoscopy shows anulation tissue on both cords, with a large mass of anulation tissue in the interarytenoid space and œdema the ventricular band.

Dec. 30th, 1927: Treatment with benzyl cinnamic ester mmenced. Patient is practically aphonic, and his mperature reached 99·5° most evenings. By the sixth y of treatment marked improvement was noticeable in s voice. Patient felt very much better than he had for me time. By the end of the course the improvement in s voice was very marked, though there was still some arseness. There was no longer any pain in the throat, r was there dyspnœa. The laryngeal appearance was rdly changed. By the end of the second course of injecns the voice had become stronger, the discomfort on allowing had completely disappeared, and laryngoscopy so revealed improvement. The interarytenoid swelling d almost entirely disappeared, the œdema diminished nsiderably, and the deposit on the cords was smaller. e patient increased 2 lb. in weight, and his general ndition was improved. He felt stronger and his appetite s now quite good. Physical signs in chest unchanged. Result: Improvement.

Apart from these, three other cases of glands in e neck were treated, two of these cases having scharging sinuses. All cases showed improvement, e sinus healing rapidly. Two cases of renal berculosis with cystitis and two cases of tuberculous ididymitis showed definite improvement in the neral condition and relief of pain and diminution toxæmia. Two cases of chronic pulmonary berculosis showed marked improvement in the neral condition after a short period of treatment ly. One case of tuberculous iritis and iridocyclitis eived so much benefit that lens extraction came possible and was successfully performed. e case of lupus vulgaris showed rapid improvement ring the first course of injections. One case of tuberous perianal abscess showed marked improvement.

Remarks.

These are all the cases treated, and they are still der observation. In reporting these cases, none which have been treated for more than three nths, I realise that it is impossible to say anything to the further prognosis of these patients, but rertheless, in that short interval of time during ich they have been under observation, improvent of some degree has been observed in *all* the es. This result seems to me very suggestive as the favourable influence of this treatment. The provement has been particularly striking in some es where the general condition was either poor definitely getting worse before this treatment was ted. In conclusion I can certainly confirm that use of Jacobson's solution of benzyl cinnamic r has given rise to no noticeable reaction, either eral or local, and that it has in all cases been fectly tolerated.

I have to thank my colleagues for allowing me to t and report on their cases and for their help in ny ways.

Clinical and Laboratory Notes.

A NOTE ON BACTERIOPHAGE FROM CASES OF RICKETS.

By T. Redman, M.Sc. Lond., M.B. Liverp.,
Lecturer in Public Health Bacteriology, University of Liverpool.

Since bacteriophage is known to be present in the intestinal tract and may play a mysterious but important part in the resistance of the individual to disease, I thought it worth while to test a few samples of fæces from cases of rickets for the presence or absence of bacteriophage. The test was accordingly done on 15 cases which were all under treatment, but in different stages according to X ray findings. The following technique was adopted:—

Fæces were incubated in peptone broth for 18 hours at 37° C., filtered through filter paper and then through a Chamberland filter. Each filtrate was then tested against four-hour cultures of typhoid, paratyphosus B, Shiga, Hiss, and Flexner. A standard loopful of culture was rubbed over an agar slant and 5 drops of filtrate run over the slant, which was then incubated for two hours at 22° C. and 18 hours at 37° C. To judge the strength of bacteriophage the following code was used:—

0	No action.
†	A few plaques.
††	Many plaques, but countable.
†††	Only isolated colonies of bacteria.
††††	An occasional colony.
†††††	Slant remains sterile.

It was found that a laboratory strain of typhoid was acted upon in several instances. As this is most unusual, a second more recently isolated strain was included in the tests and called "typhoid H." The table shows the results obtained, controls being sterile in all cases.

Bacteriophage Experiments.

No.	X ray.	Typhoid.	Hiss.	Shiga.	Flexner.	No.	X ray.	Typhoid.	Hiss.	Shiga.	Flexner.
1	Heal.	†	†††	†††	0	9	Cured.	0	0	0	0
2	Sev.	†††	††	††	0	10	,,	0	0	†††	††††
3	Imp.	†††	†	†	0	11	Imp.	†	†	†††	††††
4	Cured.	††	††	††	0	12	,,	††	††	†††	††
5	Sev.	0	†	?†	††††	13	Cured.	0	0	0	0
6	,,	0	0	?†	††††	14	Sev.	0	0	0	0
7	Cured.	††	††	††	†	15	Cured.	0	0	†	0
8	Imp.	††	††	††	0						

Typhoid H.—Expt. 12, †; in the other experiments, no action.
Para-B.—No action in any experiment.
Heal. = healing; sev. = severe; imp. = improved.

No important differences in the bacteriophage present were noticeable in these cases, although the disease was in different stages. Nor does the absence of bacteriophage active against the cultures tested appear to differentiate "cured" cases from a severe one. Activity against Hiss, Shiga, and Flexner is common in fæces from normal people, and was even found in a baby 12 days old.

The bacteriology of the fæces of 23 rachitic and 36 normal children was also investigated for predominance of fermentative or putrefactive organisms. The fæces of 11 out of 36 normal children showed putrefactive organisms. In rachitic children, 15 out of 23 showed putrefactive organisms in the fæces, which is a much higher percentage than in normal children. The ages of the children varied from 18 months to 4 years, and they were all on a mixed diet.

The work formed part of an investigation of various aspects of rickets which is being done during the tenure of the Virol Research Scholarship in Clinical Pathology in the Bacteriological Department School of Hygiene, University of Liverpool.

The writer has pleasure in acknowledging indebtedness to Dr. Dingwall Fordyce, physician to the Royal

Liverpool Children's Hospital, and to Colonel P. McDiarmid, superintendent of Alder Hey Hospital, for free access to cases under their charge.

A CASE OF TETANUS.

By S. M. Power, M.B., B.S. Lond.,
LATE HOUSE SURGEON, LONDON HOSPITAL.

An interesting case of tetanus, which may throw some light on the value of serum treatment, was recently admitted to the London Hospital under the care of Mr. E. C. Lindsay, with whose permission the following notes are published :—

The patient, a boy of 18, had 24 days previously punctured the sole of his foot with a rusty nail; the wound was quite small and was treated in the usual way. Seventeen days later he complained of pain and stiffness in the back, and for three days before admission there was trismus with generalised spasms. The true state of affairs was then recognised, but serum was not given for another two days, when an injection of 15,000 units was given intramuscularly. The patient was admitted to hospital the following day.

On admission he looked pale and was sweating profusely. There was typical risus sardonicus and marked rigidity of the abdominal muscles. The leg on the affected side was held somewhat stiffly extended. Passive movements in the joints were not difficult, with the exception of the ankle-joints, where dorsi-flexion was inhibited. The patient was given general anæsthesia and 20 c.cm. of cerebro-spinal fluid were drawn off; the pressure was considerably increased, but subsequent microscopic examination revealed no abnormality; 15,000 units of antitoxin, in a corresponding amount of serum warmed to blood heat, were immediately injected into the theca. As there was no pronounced respiratory embarrassment gr. ¼ of morphia was given, and a quiet night ensued.

Next day the condition was considerably worse. There was marked cyanosis, rigidity had increased, and generalised spasms began later, with flexion of the upper limbs and marked opisthotonos. Unconsciousness supervened and there was incontinence of urine. The patient was put in seclusion at midday. The spasms continued, numbering altogether about 50, but at about 7 P.M. consciousness gradually returned. Through the night spasms were very frequent and at times respiration completely ceased. There appeared to be increased sensibility to pain, and in the early morning it was deemed advisable to give morphia, which gave considerable ease; the movements ceased for four hours, during which the patient slept quietly. He was awakened by a very violent spasm but dropped off to sleep again. A fairly comfortable morning ensued, but spasms set in again in the afternoon, with considerable distress, the patient moaning loudly with each spasm. It was noticed, however, that he had regained power over movements of the jaw, was able to take fluids, and to answer questions. During the latter part of the day two doses of chloretone, grs. x. in glycerine dr. i., were given without much effect. That night a further injection of morphia gave considerable relief and a long sleep. After this definite spasms ceased.

During the following day he dozed, with occasional fits of restlessness accompanied by loud moaning. Consciousness was complete and there was no difficult in feeding. Now that the spasms had ceased, chloretone appeared to be effective in giving the patient the rest which he needed. 9000 units of antitetanic serum were given intravenously. A fairly quiet night ensued, chloretone being given three times and producing a definite effect each time. The jaw muscles were still very stiff and the head retracted. A further dose of 10,500 serum units was given intravenously on the following day. Recovery was now uninterrupted. Two more doses of serum were given intramuscularly on two successive days. The stiffness gradually disappeared.

On the sixth day after the first intraspinal injection, a well-defined erythema appeared on the back with vesication over the hips and buttocks. It caused considerable irritation and later spread all over the body. Lotio calaminæ was applied with good result and calcium lactate, grs. xxx., was given in the hope that it might accelerate the clearing up of the rash, which began to fade three days later. In the meantime rigidity had, to a large extent, disappeared, although there was still some stiffness in the muscles of the leg and abdominal wall. Recovery from this time was remarkably rapid and complete. The patient seemed little the worse for his experience, and was quite fit and able to get about the ward on his discharge to a convalescent home three weeks later.

It is a well-established fact that the longer the incubation period in a case of tetanus, the less severe are the clinical features and the better the prognosis; but in this case a relatively long incubation perio was followed by symptoms which were undoubtedl severe. For 48 hours the spasms continued at interval of 10 minutes, with the exception of two period after injection of morphia. During this time th condition was so bad that hope was lost and palliativ measures were alone considered. Once, however, th spasms had diminished in frequency and severity there was no setback.

If any conclusion can fairly be drawn, it is th value of early and large dosage with serum, par ticularly by the intrathecal route. Serous and eve purulent meningitis have been mentioned as com plications of this treatment, but must be very rar and the desperate nature of these cases would seen to justify the risk. The other point that arises is th value of morphia. This drug is not usually giver because of the respiratory difficulty, but here a least it apparently abolished the spasms, relieve the breathing, and procured much-needed rest. I might be considered an important factor in th recovery.

A CASE OF
EPILEPSY CURED BY OVARIECTOMY.

By R. R. S. MacKinnon, M.B., Ch.M. Sydney,
NEW SOUTH WALES.

This case seems to adduce evidence that dissocia tion of personality may be determined, in some case by alterations in the balance of the internal secretion of the ductless glands.

Two years ago I was asked to see a girl of 13 years. had attended at her birth and had attended the fathe mother, and other children for many years.

The child had suddenly developed a true epilept condition coincidentally with or shortly after the establis ment of her first menstrual activity. After a few weeks surveillance and treatment by the usual methods I aske the parents to seek further advice. They chose a doctor considerable knowledge and experience, but drugs an suggestion had no effect on the case. The child progre sively developed more frequent and more severe fits, an sank into a mental state of vacancy, irrational irritabilit and general mental and physical deterioration.

After 15 months' treatment, during which time I encou aged by suggestion all the efforts which were put fort the parents asked me to take over the case again. At th time a diagnosis of appendicitis had been made and confirme by X ray report. I presumed, with great diffidence, t disagree with this, as the clinical signs did not accurate endorse the diagnosis.

I took the following view of the case: Because the syn ptoms of epilepsy evidenced themselves at the onset menstruation in a formerly normal child, expressed then selves with greater violence at each menstrual epoch, an became worse and worse as the fuller establishment of th active reproductive powers came on; because she develope a pronounced enteroptosis of all abdominal viscera, possib due to endocrine derangement; because she was developin an enlargement of the thyroid, which had progressed about the size of a medium-sized apple, and because th thyroid is a friendly antagonist to the ovary; therefore seemed fair to opine that the symptoms were due to over-secretion from the ovaries, and that the tenderness ov the right side of the abdomen might be due to an abnorm ovary, not a pathological appendix. Further, that if it a legitimate procedure to remove half a thyroid for hype thyroidism, then it should be regarded as right to remo half the ovarian tissue in a hopeless case of this descriptio I put the position before the parents, and they were conte to leave the case to my judgment.

Dr. Steer Bowker consented to perform the operation an the site was approached by a median incision. The append was free and normal, but somewhat congested, like adjacent parts; this proved to be due to the state of th neighbouring ovary. The appendix was removed and th right ovary exposed and found to be at least twice the norm size, covered with multiple cysts, and congested. It w removed. The left ovary was normal except for one cy about half the size of a pea. This cyst was destroyed.

After the operation the whole facial aspect of the patie changed with miraculous rapidity. She lost the vacant loo which had been becoming more and more constant an marked and her intellect exhibited a marked "quickne

the uptake" under test conversations. *In six days the itre had entirely disappeared.*

In the second week of convalescence she had one attack unconsciousness, lasting four minutes and not accomnied by a fit.

Since then she has progressed, mentally and hysically, by leaps and bounds, as is shown by the llowing letter from her father four months after the peration :—

"It is a great delight to report the progress Joan has made cently. There has been a most wonderful change in her nce her operation. She is now an alert, bright, happy girl, king a very keen interest in her sewing, reading, music, and ench; in fact there is nothing that she is not interested . Physically there is also a great change. She has gained lb. since her return home, being now 9 st. 3 lb. in eight. She has a lovely fresh bloom on her cheek, and to all appears a most healthy girl. There has been no recurnce of any fits of temper or attacks of any description since r return."

The girl's health is perfect; her functions are curate. The enteroptosis has disappeared. Her terest in surroundings is identical with that exhibited any normal healthy child of her age. Her intelctual quickness and sense of humour are above the verage.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

A MEETING of this Section was held on April 24th, th Dr. A. F. HURST, the President, in the chair.

paper on the

ÔLE OF THE KIDNEY IN NON-RENAL DISORDERS.

as read by Prof. I. SNAPPER, of Amsterdam, who aintained that the kidney was not an excretory gan only, and that it was possible to talk about it a long time without mentioning the word excretion d using only the terms oxidation and metoxidation. was a most important factor in the normal etabolism of fat, and the metabolism of abnormal mostly took place there also. The kidneys must looked on as the principal organs where destruction ketone bodies occurred. Insulin had been found have a wonderful effect on diabetic coma, but from ne to time cases were met with in which insulin uld clear up all the hyperglycæmia, high ketonæmia, d acetone and diacetic acid in the urine, and yet e patient remained drowsy and died after one, two more days of drowsiness. Most clinicians explained ese cases as due to the impaired circulatory system; hough the abnormal constituents of blood and ne ceased, the cardiovascular symptoms remained. of. Snapper did not deny that these played an portant part, but renal symptoms could be disvered as well in many of the cases. Albuminuria s often present, and to some extent went parallel th the degree of ketonæmia. Both would reappear gether if the treatment were dropped. Külz had inted out that a symptom which might be regarded a signal of diabetic coma was a shower of renal sts. This proved that there was a connexion ween diabetic acidosis and impaired renal function. many cases of diabetes there was retention of urea the serum, and urea-retention was not infrequent diabetic coma. It had been suggested that oliguria ounted for this; if no water was being excreted urea had, of course, to accumulate in the blood. ulin had an influence upon the excretion of water, ducing oliguria, and possibly this anuric coma was a certain extent caused by insulin treatment. It s certainly much more frequently encountered ce the introduction of insulin. The explanation was , however, satisfactory, for diabetic coma might accompanied by polyuria with symptoms of urea-ention. Others had suggested that the urea-ention depended on abnormal protein metabolism, but this was not so. It had been proved that in these cases there was impaired excretion of nitrogenous substances by the kidneys during the coma. This was one of the most salient proofs that the function of the kidneys was impaired during diabetic coma. It was easy to suppose that excretion of all sorts of substances was also impaired. An early diabetic case which had been wrongly treated might form very large amounts of ketone bodies through inadequate nourishment. The hyperproduction might be so extensive that intoxication resulted even although the mechanism was unimpaired. Insulin would cut off the hyperproduction of ketone bodies and so cure the case. In an old diabetic, on the other hand, there had been prolonged intoxication and all the organs were impaired, including the kidneys. In this case a moderate production of ketone bodies would cause coma. Insulin would stop the ketonæmia, but the degenerated organs remained, and the patient died of impaired kidney function, of which the ketones were an indication. Pathological evidence of the impaired kidney function was not lacking. Coma kidneys had peculiar features, including a characteristic glycogen degeneration of the tubules. They were large and yellow, with fatty degeneration. There was often also a specific necrosis of the descending part of Henle's loop, hardly ever seen in any other kidneys.

The Swedish clinician Petrén had found that many acidotic diabetics could be treated satisfactorily with a high fat diet, provided that the proteins were strictly reduced. Fats were the main source of the ketone bodies in diabetic intoxication, and so most authorities restricted them, but Petrén had convinced those who had seen his work that this was unnecessary provided that the protein were reduced to 20 or 30 g. daily. Even a slight increase on the protein allowance would result in severe acidosis and coma. The elimination of nitrogen by the kidneys was their most difficult task, and Petrén's diet was one which spared the kidney function, so that the organ could destroy any amount of ketone bodies. It might be described as an alleviation diet for the kidneys.

Discussion.

Dr. R. D. LAWRENCE said that in his experience the case of diabetic coma which insulin could not cure was the case with marked circulatory deficiency rather than one with slightly damaged kidneys. It was an exception not to find casts and proteinuria in patients with diabetic coma, but the prognosis depended essentially on the condition of the circulation. It was almost possible to state from the start by the feel of the pulse whether the case would go into coma. He did not think it was proved that the small degree of proteinuria present really drove the patient into coma. Quite a number of diabetics had mild renal trouble and always passed some protein or casts; there was no proof that these were more liable to ketosis and coma than other cases. He agreed that oliguria was often present, but put this down as much to low blood pressure, making it impossible for urine to be secreted, as to any severe permanent kidney damage. He did not think any more ketosis was produced by a high protein and low fat diet than by Petren's diet. He asked if there were any quantitative data available as to the amount of ketone bodies secreted by the normal person, the nephritic, and the diabetic respectively.

Dr. E. P. POULTON said that in six out of nine cases of coma taken at random there was oliguria. He did not think that insulin quite explained the undoubted frequency—indeed, almost regularity—of diabetic coma. He had regarded the circulatory changes as the most important factors. A necessary part of the treatment of coma was to give large quantities of fluid, and this was not sufficiently emphasised. The fluid should be put into the alimentary canal. English physiologists had always regarded the liver as the organ which broke down harmful aceto-acetic acid into harmless β-oxybutyric acid, and he asked why Prof. Snapper had ascribed this function to the kidney.

Dr. GEORGE FAHR described recent work in the United States and in Germany, tending to show that the circulatory failure was a very important factor in diabetic coma. Measurements of the vital blood volume by the Congo-red method showed that fluid was lost from the system into the tissues, the blood pressure fell, the pulse became very rapid and of small volume, and the condition corresponded to that of advanced shock. Tannhäuser, in the Düsseldorf clinic, had found that the circulatory volume was quite remarkably decreased in diabetic coma, even to one-third or one-quarter of the normal, especially in those cases where insulin had been given without success. Sometimes it was impossible to restore the volume, and those were the cases that died. Where it had dropped definitely, nothing on earth would save the patient.

Dr. P. J. CAMMIDGE asked for some light on the statement that ketone bodies were destroyed by the kidneys. The whole difficulty about death from diabetic coma arose from regarding the condition as an entity. There were at least three or four varieties of diabetic coma, due to ketosis, to the kidney condition, to some failure of de-aminisation in the liver, and so on. He had known a patient die in coma without ever having had acetone bodies in the urine. Some 60–70 per cent. of patients had an increase of urea nitrogen, uric acid, &c., and often of creatine as well, so that there was a difficulty in excretion long before the onset of coma. Patients who developed coma were those who had a high urea nitrogen in the early stages; after treatment by insulin they relapsed. For this reason he had made a practice of restricting the nitrogen in the diet, which he believed to be as important as restricting the carbohydrate. Treatment must, however, depend on the type of patient; those with defective thyroid function required much more careful attention. Insulin might lead to a localised œdema, but later on many patients passed increased quantities of urine, even up to 9 litres daily. This was due to the fact that insulin combined chemically with the secretion of the pituitary. The total load the diabetic could manage was strictly limited, and any increase of either protein or fat must be accompanied by a decrease in the other.

Sir JOHN BROADBENT suggested that attention should be paid to the amount of ketone retained in the blood rather than to that passed in the urine. He asked whether ammonia played any part in neutralising fatty acids. Often a diabetic with albuminuria went on for a very long time, sometimes passing much albumin and much sugar. He asked what was the relationship of the amount of ketone bodies in the blood to that excreted in the urine in the diabetic and the normal subject.

Dr. PARKES WEBER asked whether any attempts had been made to raise the blood pressure in diabetic coma, and if so, with what success.

Reply.

Prof. SNAPPER, in reply, quoted a case with nothing abnormal in the urine save a trace of diacetic acid, who yet had 400 mg. per litre of diacetic acid and 500 mg. per litre of oxyacetic acid in the blood. The daily quantity of urine was normal. He asked how the death of this patient in coma could be explained on the circulatory hypothesis. Post mortem the kidney had been a typical coma kidney. A very rare symptom-complex in clinical medicine was that consisting of urea-retention with no oliguria, combined with low blood pressure. It was quite peculiar to renal insufficiency, which had nothing to do with a granular kidney. Cardiovascular symptoms without renal symptoms would not explain all the cases encountered. Renal difficulty could be demonstrated in a coma case by the phenolsulphophthalein test, which would reveal delayed excretion seven or ten days after "cure" by insulin. Very small amounts of protein could bring about disbalance between carbohydrate and fat. Obviously if the kidney had only a small amount of water at its disposal it could only excrete a small amount of toxic substances. Th opinion that the liver acted on diacetic acid had bee based on inadequate perfusion experiments. A dog liver perfused with 500 mg. of β-hydroxybutyric aci yielded up only 100 mg. at the end, and 200 mg. diacetic acid. It was therefore assumed that th 200 mg. which had disappeared had been oxidise In those days it was impossible to analyse the liv substance. With modern biochemical methods it wa possible to prove that the liver absorbed the missin 200 mg. of β-hydroxybutyric acid during the exper ment. It did not absorb diacetic acid, because th surface tension was quite different. If the liver wer perfused with diacetic acid the liver would be foun to take up a good deal of it in the form of β-hydrox butyric acid. If benzoic acid were perfused throug the kidney with glycocoll, hippuric acid resulte There was a whole series of homologues of benzoic aci each with one CH_2 group more than the one belo These groups had been named α, β, γ, and so o In vitro oxidation in the β group had for long bee unknown, and therefore it had not been recognised i vivo. Now it was known that β fatty acids are oxidis in the organism. If a dog's kidney were perfus with β-hydroxybutyric or diacetic acid a lar amount would disappear—some 160–200 mg. in tw hours—so presumably a man's kidney, working f 24 hours, could oxidise a considerable quantity. A fat normally digested went through β-hydroxybutyr and diacetic acid stages. These were not found normal urine, being destroyed by the kidneys.

SECTION OF EPIDEMIOLOGY AND STAT MEDICINE.

LATER PHASES OF ENCEPHALITIS LETHARGICA.

A MEETING of this Section was held on April 27t when Dr. MONCKTON COPEMAN took the chair, and discussion on Post-encephalitis and its Problems w opened by Dr. ALLAN PARSONS.

Ten years had now passed, he said, since encephali lethargica was first recognised in this country. Sin then something had been learned of the epidemiolo of the disease, its sporadic occurrence, its comparati prevalence in the colder months of the year, i special incidence in adolescence, its impartiality f the sexes, its indiscriminate incidence in all soci grades, and its seeming independence of insanita conditions. Much had still to be learned about t way in which it spread, its epidemiological relatio with other diseases, and its relatively high inciden in this country as compared with abroad. The clinic zeal first brought to bear upon the strange syndro was still needful, since differential diagnosis might difficult, and the primary attack so slight as to esca recognition. The disease was really of small p portions, however; in 1926 encephalitis lethargi attacked only 0·06 per 1000 of the populatic and though the case-mortality was certainly hig the toll it took of the general population in 19 was only 34 per million living, as compared with 9 and 1362 respectively for tuberculosis and cancer.

Types of Case.

By post-encephalitis Dr. Parsons meant th chronic phase of the disease which often su ceded the acute attack and was marked various symptoms which might be relics, resid or after-effects. From the administrative po of view it was useful to classify the suffer rather than the sequels, and he grouped the into three classes: those with mainly physi sequels, those who chiefly showed mental deterio tion, and those who exhibited demoralisation. Amo the physical sequels none was so well known Parkinsonism, which was so common and import that it was regarded by some as almost synonym with post-encephalitis. One table which he show indicated mental sequelæ in 27 per cent. of cases, t this was probably an under-estimate, and in t Sheffield outbreak (1924) mental symptoms were s to have remained in 53·6 per cent. Post-encephali

tients with mental symptoms might broadly be vided into the excitable and restless and the pressed. The former included the very common cturnal restlessness with inverted sleep rhythm in ildren. In lists of the sequels of encephalitis in ildren this disorder appeared always first or second frequency, and probably occurred in 76 per cent. of venile post-encephalitis. An altogether different cture was presented by the passive or depressed pe of patient. Inability to make any progress at hool was due to dulled intelligence, impaired emory, and perhaps drowsiness, rather than to the stlessness, impatience, and lack of concentration hich made teachers despair of the excitable type of ild. Children in the advanced stages of Parkinnism provided examples of the passive type of case, t it was mainly adult patients who suffered from ental anergia. The mental disturbance in both pes of case might be severe enough to justify rtification; the irritable, mainly for the sake of hers, were admitted to institutions as suffering om hallucinations, with homicidal tendencies or ania; while the depressed, mainly for their own ke, were admitted by reason of melancholia, suicidal pulses, or complete dementia. In the third class, ose who exhibited demoralisation, to speak of anges in conduct was almost to speak of postcephalitis in children, but intellect in such children s often unimpaired, and in fact they might even pear strangely bright.

Care of Children and Adults.

Patients with post-encephalitis might conveniently divided into two classes, according to whether the ness began before or after the age of 18. It was en difficult to decide whether the advantages of eping a post-encephalitic child working as far as ssible among normal children were not cancelled the disadvantages to the other children arising m the presence in their midst of one or more pupils ose conduct and disposition had become abnormal. nerally speaking, except when children had only nt traces of their illness, a return to their usual hool was impracticable. For some the schools for ckward and mentally defective children would ovide the extra individual attention and patience cessary to re-educate the diminished power of ncentration and arrested intellectual development. om 1920 to 1927 the Home Office schools received 13 children of this type; of the 57 discharged, 5 showed no permanent improvement, and of the 4 remaining (2 had died), 10 were considered unsuite for further retention. Attempts to train such ldren in Home Office schools were not justified by results obtained. In any case committal to Home ice schools was for a limited period only, and the ng offender—if he had not meanwhile come under Board of Control—must eventually be released, l either passed into employment, sent home, or ced under the care of guardians. Up to the end last year the post-encephalitic delinquents usually l no difficulty in avoiding the Board of Control ause many of them were not considered mentally icient, and because, where there was undoubted iciency, this had not existed from birth or early , and the patient therefore could not be certified ording to the liberal interpretation of the Act. th the passing of the amended Mental Deficiency , however, the technical difficulty of the principal was removed, and this with the new definition "moral defectives" should prove helpful in ling with troublesome post-encephalitics. In the jority of cases the disposal of the patient in a table mental deficiency institution was probably best course.

Dr. Parsons next described the position of the dult who returned home after prolonged illness in pital. The family realised that the returned ient had altered in various ways and did not me his accustomed rôle. He might be subject to less wandering, confirmed melancholia, lost initia, impaired memory. Difficult problems were thus duced in the domestic circle, and when the powers and patience of the relatives reached breaking-point the removal of the patient from home became urgent. There was often, however, much difficulty in finding a suitable refuge. A certain number, by reason of melancholia, suicidal impulses, or general insanity, became certifiable, and found asylum either in mental hospitals or in the mental wards of poor-law institutions. Sufferers below the age of puberty might be placed under special care and homely discipline. An institution like the post-encephalitic unit at the Metropolitan Asylums Board's hospital at Winchmore Hill, offered some hope of improvement for the less demoralised juveniles. Some of the difficult cases who had reached puberty would in future be dealt with under the Mental Deficiency Act, 1927. The adult patients, as a class, did not require re-education and control so much as relief from anxiety and expert attention to their physical needs. For the large majority of such the poor-law institutions offered a refuge. In Bristol, Glasgow, and a few other places the local guardians had recognised the needs of post-encephalitis patients, and in collaboration with other local bodies had made special provision for them. The Board of Control had also realised that patients whose mental symptoms were due to encephalitis lethargica needed particular study, and provision for such patients was made at the West Park Hospital, Epsom, and at four or five other mental hospitals in the provinces. In conclusion, Dr. Parsons urged the necessity for further research to include the coöperation of all those interested in this subject, whether from the administrative, clinical, or any other point of view.

Discussion

The PRESIDENT said that Dr. Parsons had painted a somewhat depressing picture, but had rightly laid stress on the fact that the actual number of cases was relatively small. It seemed regrettable that notwithstanding all the work of clinicians and bacteriologists during the last ten years so little was known about this disease. It could not even be prophesied what was likely to happen—whether such a peak of the disease as occurred in 1924 was to be repeated. He wondered whether any means of treatment had been worked out along similar lines to the malarial treatment of general paralysis of the insane.

Dr. F. C. SHRUBSALL gave some recent statistics for London, concerning 403 cases which had been investigated during three years. Of this number 227 were still showing definite after-effects; 76 of these were paralysed or had Parkinsonism, and 105 were mentally or morally affected. The death-rate during the whole period had been 37 per cent.

Dr. J. D. ROLLESTON raised the ætiological question as to whether this disease attacked any particular class of persons. The suggestion had been made that it attacked those who had already some mental taint, but that view could not be sustained.

Dr. GRAHAM FORBES asked whether the mild cases were not liable often to develop the more serious sequels. He also mentioned an instance of familial susceptibility—a brother and sister (adults) both being infected, though at the time of the sister's infection and death the brother was abroad, developing the disease on his return home.

Dr. N. G. HILL mentioned a case in which malarial therapy was tried, but the patient became much worse, though there was slight relief at the close when quinine was used.

Dr. D. S. SUTHERLAND said that the late features might develop in quite slight cases. Ultra-violet baths seemed to act as an excellent tonic in such cases, but the cases in hospital were most benefited by the discipline and regimen of hospital treatment.

Dr. W. S. C. COPEMAN asked whether he was right in supposing that the only aspect of the post-encephalitic syndrome which interested the public authorities was the mental deficiency. Did the post-encephalitis unit include anything like systematic treatment of the other disorders, such as insomnia and salivation?

Dr. THOMAS CARNWATH had noticed that where the infection seemed to persist for many months

another case might eventually occur in the same home. The authorities responsible for treatment only burdened themselves with such cases as were referred to them by the school authorities or by the parents through difficulty in control either at home or school, and there were no doubt a good many cases with minor defects which did not come under the authority.

Dr. CLARK TROTTER said he had had to employ sanitary inspectors to elicit the information about the after-history of cases required by the London County Council, and as a consequence of Dr. Parsons's paper he would study their returns with more attention than he had so far devoted to them.

Dr. PARSONS, in a brief reply, said that the path of infection was probably through the nose. He had not been able to find that food was a source of infection. As a general rule the mild case did not give the bad sequels. Most of the bad sequels followed a severe primary attack.

Reviews and Notices of Books.

PROTOZOOLOGY.

Lehrbuch der Protozoenkunde. Founded by FRANZ DOFLEIN. Fifth edition. Revised by Prof. Dr. EDUARD REICHENOW, Departmental Director at the Institute for Marine and Tropical Diseases, Hamburg. Part I. Allgemeine Naturgeschichte der Protozoen. Jena: Gustav Fischer. 1927. Pp. 436. M.21.

THE fourth edition of this well-known text-book of protozoology was published in 1916, a few years before the death of the author. Since then many important changes have occurred in our conception of the protozoa, so that a fifth edition, revised by such a well-known protozoologist as Dr. Eduard Reichenow, will be welcomed. The book is divided into two sections, the first dealing with the natural history of the protozoa in general, and the second with the systematics of the group, and the special natural history of individual organisms and groups of organisms. The first section has been issued as a separate volume, the second section being promised for an early date.

The volume is divided into five parts—general morphology and physiology of the protozoa, reproduction and development, œcology, technique, and literature. Under these headings an excellent account of the general features of the protozoa has been given. As in previous editions, the subject has been dealt with from the purely zoological standpoint, and though due reference to parasitic forms, including those which produce disease, is made, no special emphasis is given to them. The text is clear, the general arrangement is good, and the 388 illustrations, many of them appearing in this text-book for the first time, are admirably selected. The discussions are lucid and well balanced, so that the whole account faithfully presents the modern aspect of the subject. The author favours the view that protoplasm is structurally a colloid. He adheres to the unicellular conception of the protozoa for, though it is evident that as an individual organism a protozoon corresponds with one of the higher multicellular organisms, this does not prevent a protozoon, from another point of view, being regarded as corresponding with a single metazoan cell, which in many cases conducts itself as a single protozoon. In connexion with nuclear division important recent work on the behaviour of chromosomes and centrosomes is reviewed and illustrated, while the subject of chromosome reduction in connexion with syngamy is carefully discussed in the light of recent work. As regards extranuclear chromatin great importance is attached to Feulgen's reaction which affords a reliable test of the nature of any granule in the cell. By its means it has been possible to exclude from chromatin many granules which were supposed to be of this substance. The recent work of Dogiel on conjugation as it occurs amongst the ciliates which inhabit the intestinal tract of ruminants is noted. Developmental cycles, regener tion, variation, and heredity are fully discussed, whi under œcology sections are devoted to a considerati of incidence and geographical distribution, mari and fresh water protozoa, soil protozoa and parasit protozoa, with special reference to the origin and ty of parasitism, the influence of parasitism on t organisms themselves, the relations between host a parasite, the transmission of parasites, and finally t parasites of protozoa. In the technical section a described the most important methods which a required for the study of the free-living and parasit protozoa, as also the more recently devised process for the cultivation of the parasitic forms. The refe ences to literature are classified according to the ma subdivisions of the book. There is no index, but o will doubtless be issued with the second part, t intention evidently being to bind the two together t form one volume.

The work will be widely read, and will form standard for reference and study for all serio students of protozoology.

THE ESSENTIALS OF OTOLOGY.

By GEORGE BIRMINGHAM MCAULIFFE, A.B., M.D F.A.C.S., Assistant Professor of Otology, Corne Medical College. London and New York Humphrey Milford, Oxford University Pres Pp. 177. 16*s*.

Dr. McAuliffe holds that the majority of books o this subject are written to show the full scope otology, are suitable only to the specialist, and includ much information that the general student will nev read and never use. He is surely in error here, f there are many excellent small manuals on otolog especially written to satisfy the needs of the stude and general practitioner. The book before us can b fairly ranked among these; the style of writing didactic, as it must necessarily be in a concise wo of this kind, but the teaching is, on the whole, a reliab reflection of present opinion, though there are, course, a few points which will not meet with univers agreement. Thus, he uses no stitches after t "acute" mastoid operation, but leaves the ski wound entirely open; he appears to recommen syringing as the regular treatment of acute suppurati otitis after spontaneous or surgical perforation the drum; and for the diagnosis of adenoids b considers digital examination the best method, an does not describe posterior rhinoscopy at all. T chapter on anatomy, which he thinks may discoura the student, has been relegated to the end of t volume. The rather inconvenient method has bee adopted of discussing treatment in a separate chapt towards the end of the book; this leads to ove lapping, compels the student to refer to two separa places for one subject, and in one case at least, th of furunculosis, appears to have led to the omissi of treatment altogether. We believe that mo students would prefer a work arranged in a mo orderly manner, but practitioners may find t arrangement less inconvenient.

TEXT-BOOK OF CLINICAL NEUROLOGY.

By ISRAEL S. WECHSLER, M.D., Assistant Pr fessor of Clinical Neurology, Colombia Universit New York. London and Philadelphia: W. Saunders Company. 1927. Illustrated. Pp. 72 32*s*. 6*d*.

THE purpose of the author has been to set down straightforward fashion a digest of nervous diseas as they are known and recognised to-day, and b book has grown out of his own clinical experienc and embodies what may be termed his person approach to bedside neurology. It follows accept lines in covering all the usual diseased conditions brain, cord, and peripheral nerves, and it includ sections on affections of the vegetative nervo system, developmental anomalies, the neuroses, a other "functional" states such as tics, spasms, a myoclonias. Possibly its outstanding feature is t

tention given to the pathological bases of these ervous diseases, which are illustrated as far as may e by a series of excellent photographs. The clinical ustrations, fewer in number, are also good. In ifferent chapters some effort is made to elucidate the ysiology of the symptoms described, notably in gard to the difficult group of striatal diseases, so lled, and this is well done even if knowledge has ot yet sufficiently advanced to allow of very definite nclusions to be drawn. Some 100 pages are assigned methods of examination, a section seemingly held be a sine qua non of neurological text-books; in is instance, however, it consists in large part of an terpretation of symptoms and signs.

Dr. Wechsler's book is readable and remarkably ide in its range, but at the expense of rendering me of the disease descriptions rather meagre and me of the semiological interpretations rather super-ial. Of this the neurologist soon becomes aware as reads through its pages; on the other hand, it rves its purpose well, and for the student and prac-ioner it appears to constitute a useful compendium practical neurological medicine.

HE SPRINGS OF HUMAN ACTION.

By Prof. MEHRACK THOMPSON. London and New York: Appleton and Co. 1927. Pp. 501. 10*s.* 6*d.*

IN spite of the vast literature that is growing up psychological topics, there appears still to be room r books dealing with psychology in general. Both iblisher and public are apt to grow weary of this er-increasing pyramid of literature. But as long each author presents his subject from a new angle great harm is done. Particularly so to-day, eing that the new orientation in psychology—the namic standpoint—is hammered into the minds of ose who await instruction. It is for this reason at Prof. Mehrack Thompson's book deserves a lcome. Whereas Dr. J. B. Watson's psychology s reduced man to a physiological Robot—reflecting, doubt, the material success of the New World of. Thompson represents the young and enthusiastic nerican overflowing with creative will. He attacks ychology from the point of view of motive. He ens with the Urge of Physical Activity—Automatic ts—Habits and Instinctive motive, and passes wards in crescendo to the more complex springs actions—feeling—interest—ideas—personality—all garded as psychological complexes which reinforce, ect and redirect the fundamental drives. Later, e group activities are themselves used as motives action, and here suggestion and auto-suggestion me to full flower in the author's opinion. As can expected, this treatment of the subject leads to an traordinary amount of repetition. The lowest ocesses, as we have discovered in the study of ychopathology, are always present in the highest our activities, and it is not always possible to say at at a given level the complex situation at the oment is acting as a whole and in virtue of its n intrinsic properties, or whether it is still driven ward by fundamental urges.

The result is that we are obliged to read through a ry large book which might with very little sacrifice usefulness and readableness have been reduced to lf its present size.

OSQUITO REDUCTION AND MALARIA PREVENTION.

Second edition. By J. A. CRAWFORD, M.B., Ch.B. Edin., Capt. R.A.M.C.; and B. S. CHALAM, L.R.C.P. & S. Edin., L.R.F.P. & S. Glasg. London: Humphrey Milford, Oxford University Press. 1927. Pp. 107. 4*s.* 6*d.*

THIS small book is written for the benefit of the alaria inspector, the N.C.O. in charge of an anti-alaria sanitary squad, or indeed of everyone whose siness it is to destroy the anopheline vector of alaria, and who requires sound elementary know-ge to make his action effective. The book meets e demand; it is clearly written, satisfactorily ustrated, and has always in mind the practical daily needs of the field-worker. Among the useful appendices is a key to the female Indian anophelines, issued by the Central Malaria Bureau, Kasauli, while in the text there is a table showing their breeding habits and their distribution in India, together with comments which include an indication of those species which are actually malaria carriers.

The authors tend to stress those aspects of anti-malarial work with which they are mainly concerned—one sentence might be read as advice to discard mosquito nets, while elsewhere they throw doubts on the value of quinine in the fight against malaria. A suggestion, in spite of the book's title, that for the abolition of malaria an area must be rendered free of mosquitoes, is open to criticism. These points will perhaps be cleared up in a third edition. This, too, will afford the opportunity to eliminate such unexpected spellings as "larvacide," "*Stegomya faxiata*," and "*A. azriki*," and to rectify the slip which, in one place, mentions as masculine the adult anopheles sought for in houses.

The book is one of several, of varying range and size, which have recently appeared dealing with malaria in India. It could give good service elsewhere, and it forms a useful reminder that the malaria problem is essentially the same everywhere, and that other tropical parts of the Empire are unwise which do not take full advantage of the pioneer work which India has to offer them.

THE PEAKS OF MEDICAL HISTORY.

Second edition. By CHARLES L. DANA, A.M., M.D., LL.D., Professor of Nervous Diseases, Cornell University Medical College; ex-President of the New York Academy of Medicine. New York: Paul B. Hoeber. 1928. Pp. 105. $3.

THE last few years have seen a revival of interest in historical medicine, of which the demand for a second edition of Prof. Dana's book within two years of publication is proof. The author sketches briefly and clearly the progress of medical science from the time of Hippocrates to the middle of the nineteenth century, illustrating his text generously and well. For such of his readers, and we think there will be many, who are encouraged to dip more deeply into the subject, Prof. Dana adds a chapter of biographical notes.

JOURNALS.

NATURE. No. 3051. Vol. CXXI. April 21st, 1928. A supplement to this issue contains a series of concise articles by various authorities on different aspects of ultra-violet radiation. Some of the conclusions reached are summarised below. The Physical Basis of Light Therapy, by Prof. F. Ll. Hopwood. The author describes the spectrum of radiation, discusses the light used in therapy and its sources, defines the terms photo-electricity, fluorescence, phosphorescence, and explains the laws governing photo-chemical action. Prof. Hopwood points out that the reflecting, transmitting, and absorbing powers of a substance for light give no trustworthy indication of these properties for radiations in the infra-red or ultra-violet regions. Corning glass 980A transmits all solar radiations almost as freely as the more expensive fused quartz. Vitaglass resembles Corning glass 980A in its properties, but is not so transparent for equal thicknesses and also exhibits some deterioration in transmission after exposure to sunlight. Notes on the determination of quality and of intensity of radiation follow, while dangers, precautions, and contra-indications to light therapy are clearly set out.—Biological Action of Ultra-violet Rays, by Dr. Leonard Hill. The screening power of the epidermis and the penetration of radiations of various wave-lengths are discussed. The biologically active region of the ultra-violet rays is about 300 $\mu\mu$; these are largely absorbed by the epidermis and exert their action there. Given a sufficient dose of rays absorbed, coagulation and death of cells takes place. In lesser doses the inflammatory reaction increasse the bactericidal power of the blood, stimulates

recovery from certain skin diseases, and in some unexplained way promotes general vigour and well-being. The dangers of overdosage and the need for skilled medical supervision when disease is being treated are emphasised.—The Physiological Action of Ultra-Violet Radiation and its Use in the Home, by W. Kerr Russell. The author believes that the only form of this treatment which should be used at home is exposure of the whole body to the rays, preferably by means of the carbon-arc lamp, or by means of carefully screened mercury-vapour lamps. He summarises the precautions to be taken and discusses the immediate and remote effects of radiation on the body.—Ultra-Violet Radiation for Domestic Use, by Prof. S. Russ. The author considers that it is inadvisable and probably uneconomical to attempt to make good any deficiency of diet suffered by the general population by frequent doses of ultra-violet radiation. The risk run by repeated exposure of the body to a form of radiation to which it is quite unaccustomed is not negligible, and probably it would cost less to supply the deficient accessory food factor in the diet. The public cannot be prevented from using appliances for generating ultra-violet radiation in their homes, but they should not be advised to do so.—Medical Aspects of Artificial Sunlight in Private Houses, by P. R. Peacock. The establishment of more clinics where the poor, whose diet is short of fresh foods, can be treated under supervision is regarded as a more rational measure than the installation of sources of ultra-violet rays in the homes of well-to-do people whose vitamin intake and general conditions of life are relatively good.—Articles follow on the Selection of Lamps, by T. C. Angus and by B. D. H. Watters, and on the Ultra-Violet Transmission of Transparent Materials, by L. C. Martin.

AMERICAN REVIEW OF TUBERCULOSIS. February, 1928. Vol. XVII., No. 2.—In a statistical study of the relationship between pregnancy and tuberculosis, Miss Alice M. Hill suggests that hitherto this problem has been studied by the obstetrician who has had charge of women whose pregnancy has been complicated by tuberculosis, whereas a clearer understanding should result from a study of the tuberculous woman whose disease is complicated by pregnancy. A comparison of the condition of 160 women whose pregnancies accompanied, or immediately preceded, their tuberculosis with that of controls at one year and two years after diagnosis leads to the conclusion that pregnancy had no appreciable bearing on the progress of the tuberculous disease. The prognosis is bad, however, in the case of women whose tuberculous condition is only ascertained at a late stage of pregnancy. Thus, of the women whose disease was diagnosed before gestation, less than 1 in 12 had died a year after its termination, whereas for cases diagnosed during pregnancy the proportion was 1 in 5 and for those diagnosed after delivery, 1 in 3. As might be expected, the maternal mortality-rates for tuberculous women do not follow the mortality-rates for mothers in the general population in the matter of age at death, but correspond with the deaths at different ages of all tuberculous women.—Dr. H. B. Anderson discusses the tuberculous nature of pleurisy from the life insurance standpoint. Pleurisy with effusion is almost always tuberculous. Ordinary dry pleurisy is usually tuberculous, but care should be taken to differentiate between genuine pleurisy and the numerous other conditions in which pain is referred to the chest-wall—e.g., pleurodynia, myositis, and intercostal neuralgia. Patients who have suffered from these will often give a history of an attack of pleurisy. A patient of tuberculous stock, whose own physique is poor, who is underweight or is losing weight, and who has had an attack of pleurisy, should be regarded as a member of "a dangerous group which probably never become standard lives."—Drs. Saling Simon and Felix Baum present a preliminary report on their electrocardiographic studies in pulmonary tuberculosis. As the result of their investigations they conclude that the low potential sometime found in leads I. and III. indicates the condition of *cor pendulum*, which is frequently noted in phthisical subjects of asthenic type. A weakened cardiac musculature is suggested by the height of the T-wave, which they have found to be lower than the average in tuberculous individuals.—Dr C. T. Ryder writes on Innate Resistance to Tuberculosis (see p. 920).

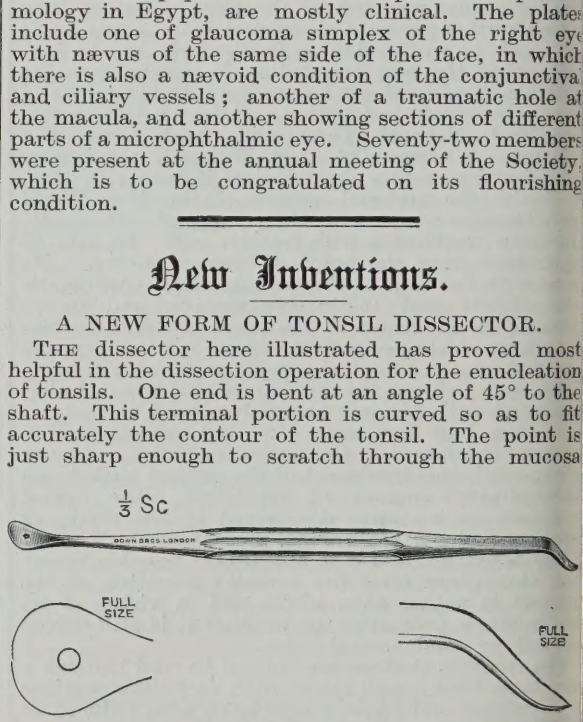
INDIAN PHYSIOLOGIST. No. 1. January, 1928.—This is a new venture in Indian medical journalism. The first number is almost wholly the product of the editor, who supplies interesting matter relating to some of the customs of Indian village life which have persisted through countless ages and for which he seeks scientific bases. He mentions, for example, the Hindu practice of worshipping the Sun God in a manner involving three 20-minute exposures of the uncovered body which resulted in many cures in devout tuberculous subjects. He explains certain native practices—e.g., the chewing of betel, as an attempt to supply deficiencies in a monotonous rice diet. If the journal is to make a wide appeal, the editor will have to be supported by the rapidly increasing number of Indian physiologists who are working on experimental lines.

BULLETIN OF THE OPHTHALMOLOGICAL SOCIETY OF EGYPT. Vol. XX. 1927.—This report runs into over 200 pages. The papers are nearly all by Egyptian-born members, while the subjects, except for historical papers on the development of ophthalmology in Egypt, are mostly clinical. The plates include one of glaucoma simplex of the right eye with nævus of the same side of the face, in which there is also a nævoid condition of the conjunctival and ciliary vessels; another of a traumatic hole at the macula, and another showing sections of different parts of a microphthalmic eye. Seventy-two members were present at the annual meeting of the Society, which is to be congratulated on its flourishing condition.

New Inventions.

A NEW FORM OF TONSIL DISSECTOR.

THE dissector here illustrated has proved most helpful in the dissection operation for the enucleation of tonsils. One end is bent at an angle of 45° to the shaft. This terminal portion is curved so as to fit accurately the contour of the tonsil. The point is just sharp enough to scratch through the mucosa



between the anterior pillar and the tonsil. Finding the correct plane between the tonsil and its bed is the key of success in this operation. This is perfectly easy in a large well-defined tonsil, but may be difficult in a flat adherent tonsil. The bent end of this enucleator makes the approach to the correct line of cleavage much easier. After the anterior pillar is separated from the tonsil the flat scoop end is inserted and the upper pole is separated and the whole tonsil stripped forward from the posterior pillar. The scoop end is admirably adapted for the latter part of the operation.

The instrument was made for me by Messrs. Down Bros., Ltd., St. Thomas's-street, S.E. 1.

THE LANCET.

LONDON: SATURDAY, MAY 5, 1928.

PURPURA OF THE URINARY TRACT.

For many years surgeons have been puzzled to account for an illness with which they are occasionally presented, characterised by hæmaturia without any other symptoms. The condition has been called "essential hæmaturia," a name which has been objected to by some observers as begging the question of ætiology, though it must be admitted that the term has the merit of indicating that our present knowledge of the disease is confined to the single fact that the urinary tract bleeds. Kidneys which have bled in this way have been removed as a life-saving measure and examined microscopically; sometimes no real abnormality could be discerned, sometimes nephritic changes have been found. In other cases the bleeding has been supposed to come from enlarged veins at the apices of the pelvis, but all the explanations hitherto have been rather unsatisfactory. Mr. FRANK KIDD, in a presidential address to the Urological Section of the Royal Society of Medicine, which we print on another page, records his own observations in such cases and helps to clear our ideas on the pathology of a curious condition. He has shown that painless hæmaturia is sometimes one expression of a general tendency to bleeding, the obvious sign of a more generalised process. Such patients are apt to bleed from other parts of the body, purpuric patches being found sometimes on their limbs, sometimes in the mucous membrane of the bladder, where they may be revealed by cystoscopy. This last observation is suggestive. Most surgeons of experience will recall unexplained cases of hæmaturia in which hæmorrhages in the bladder wall were seen on cystoscopy and disappeared later, but in which the connexion with so-called essential hæmaturia was not recognised. Mr. KIDD would divide purpura of the urinary tract into two varieties: renal purpura, where hæmorrhages take place into the mucosa of the pelvis of the kidney and lead to exudation of blood down the ureter, and purpura of the bladder wall, in which the hæmaturia is accompanied by vesical pain and irritability. The true cause of the condition is still not very clear. It is surmised that there may be a deficiency of blood platelets, as in other forms of purpura, but this question has not yet been investigated. Another possible origin is a local infection of some kind. In support of this, Mr. KIDD describes purpura as recurring in three of his cases the day after the extraction of septic teeth; he has also seen severe purpura associated with a colon bacillus pyelitis.

Turning to treatment, Mr. KIDD found that in eight of 24 cases of renal purpura a nephrectomy was required to stop the hæmorrhage. Two of these however had recurrent attacks of hæmaturia of lesser degree, and two died within a few months although one kidney had been removed. Nephrectomy is not always required. It seems that an injection of anti-streptococcic serum is often effective in stopping the bleeding; the benefit so derived has been attributed to foreign protein, and a trial of plain horse serum or peptone has met with some success. Should these injections fail it would be worth while to try an injection of the patient's own blood (auto-hæmotherapy) or, finally, transfusion from a suitable donor before resorting to removal of the kidney. If it be proved in the future that there is a thrombocytopenia in certain of these cases it would be logical to remove the spleen, for splenectomy has proved effective in general purpura associated with alteration in the platelet content of the blood. The all-important question of how to recognise the disease still remains to be settled. Painless hæmaturia has so often been thought to be due, more than anything else, to a tumour, whether of bladder or kidney, that bleeding kidneys may in the past have been removed without necessity in order to prevent the spread of a malignant tumour. If a patient has painless hæmaturia and the blood is seen to come from one ureter, if infection of the urinary tract with the tubercle bacillus or other organisms can be excluded, if an X ray shows that there is no calculus in the kidney and there is a good passage along the course of the ureter for a fair-sized bougie, then it is essential to perform a pyelography. A tumour of any size is certain to distort the shadow thus obtained. If the pelvis and calices are of normal shape there is no need to contemplate a nephrectomy on the supposition that a malignant tumour is present; it is sufficient periodically to re-examine the patient's renal pelvis. A tumour, if present, will soon indicate its existence by alteration of the shadow. Mr. KIDD'S observations have gone some way towards clearing up doubt in a condition which has hitherto been obscure to the surgeon.

THE RARITY OF MULTIPLE PRIMARY MALIGNANT NEW GROWTHS.

In his recent Linacre lecture Dr. J. A. MURRAY [1] drew attention to an important aspect of carcinogenesis. In the experimental investigation of tar cancer in mice he found that the development of a malignant new growth frequently affects the whole organism in such a way as to keep in abeyance the subsequent development of a second malignant new growth. If this observation is correct the phenomenon should manifest itself also in man by the rarity of primary malignant new growths and Dr. MURRAY has quoted some figures in support of his view. It is curious that this phenomenon has received so little attention by pathologists in the past, for there must obviously be abundant material in the post-mortem records of the big hospitals all over the world and the example quoted by Dr. MURRAY is sufficiently striking. It refers to the post-mortem material for the preceding 21 years of the Pathological Institute in Budapest. In 1559 tumours autopsies only five cases of multiple primary malignant new growths were found—i.e., one case every four years. Further evidence bearing on this point is presented in a recent paper by Prof. D. M. CHAJUTIN,[2] of the Pathological Institute of the Odessa Hospital. In two tables the author has collected from the literature figures illustrating the rarity of multiple primary malignant new growths. The first table gives their number in reference to the number of autopsies.

Feilchenfeld	507	10 (1·97)
Spranger	417	6 (1·44)

When multiple primary malignant new growths occur, they are as a rule two primary carcinomas. A combination of a primary carcinoma with a primary sarcoma is rare. More than two primary multiple new growths are extremely rare, especially if they develop at the same time. According to the author only two such cases are recorded in the literature. ROESCH [3] records in a paraffin worker, aged 72, a carcinoma of the skin, of the bronchus, and of the stomach. The other case, recorded by GÖTTING,[4] was a man, aged 58, and suffering from a carcinoma of the larynx, of the stomach, and of the rectum. Perhaps more frequently a somewhat different condition is met with where a malignant new growth has been removed by operation and one or two primary new growths develop subsequently. In one such case observed by SALTYKOW [5] a woman had been operated on for cancer of the breast. When she died a year later a carcinoma and a sarcoma of the thyroid were found at autopsy. In this case the tumours of the thyroid may already have existed at the time when the mammary tumour was removed. But it would be difficult to interpret in the same way the case observed by HARBITZ.[6] This patient first developed a cancer of the lip. This was removed by operation and 13 years later he developed a cancer of the penis. This again was removed by operation. There were no local recurrences after either of these two operations. Six years after the second operation the patient, who was then 70 years old, died with a carcinoma of the stomach. Prof. CHAJUTIN records a similar case of this kind. A woman, aged 47, developed a mammary cancer which was treated by removal of the left mamma. Eleven years later she developed a cancer of the uterus. The uterus was removed by operation. Microscopic examination showed the existence of two malignant neoplasms: an adenocarcinoma and a squamous-cell carcinoma. Quite recently Prof. A. FULLERTON [7] has described in our columns a case in which a sarcoma of the breast was followed twenty years later by an abdominal carcinoma. The rarity of such cases and the significance which attaches to them make a published record of them a matter of considerable interest.

DISTEMPER IN FERRETS.

DISTEMPER in dogs has in the past presented a very solid obstacle to all attempts to avert or lessen the force of its ravages. The great variability in severity of the disease has induced hope from time to time that methods of cure or prevention were being discovered; but the fact that distemper is extremely infectious and the uncertainty as to the result of infection in any particular puppy have for a long time almost frustrated experimental researches. The discovery by H. Carré in 1905 that the disease was due to a filter-passing virus, though confirmed by J. Lignières in the next year, was not universally accepted. The *Bacillus bronchisepticus* advocated by N. S. Ferry and others had a vogue for some years as the causal organism, but must now be relegated to the part of a secondary invader answerable for certain complications. The researches of P. P. Laidlaw and G. W. Dunkin[1] working at the National Medical Research Laboratories for the Scientific Committee of the "Field" Distemper Council have confirmed Carré's observation, though they found that filtration through Mandler and Pasteur Chamberland L 2 filters did not take place very readily and required special conditions. They have made a number of interesting and important observations on the virus and on the clinical behaviour and pathology of the disease in dogs and ferrets; they have established the identity of experimental distemper in ferrets and then atural disease in dogs and have shown that the disease in the former animals has a fairly uniform, severe, and usually fatal course. In the ferret they had available an experimental animal which bred more rapidly than the dog, was much smaller, more easily housed and reacted regularly to experimental infection. The extreme infectiousness of the disease and consequently the great care needed in isolation, however, still provided formidable difficulties to their work. It was found that a susceptible ferret could not be kept in the same small room, 7 ft. 6 in. by 5 ft. 6 in., with an infected animal without becoming infected also, although the two ferrets were placed as far apart as possible and great care taken to avoid accidental transference. The infection appeared to be carried through the air. In spite of these difficulties experimental research has been possible, knowledge has gradually accrued, and a prospect of preventive inoculation is coming into view. In the most recent paper [2] by Laidlaw and Dunkin a definite and highly successful method for the prophylaxis of the disease in ferrets is described. The virus used in making the vaccine consists of ground-up spleen from ferrets killed on the fourth or fifth day of illness. Several methods have been used to render the virus non-infective for use as a vaccine. Heating, storage in 50 per cent. glycerine and treatment with phenol or formalin are all in some degree suitable, but the use of 0·1 per cent. formalin subsequently neutralised with ammonia has been adopted as the usual procedure. Formalin has been employed partly in consequence of the success which has been obtained with formalised virus in protecting guinea-pigs against foot-and-mouth disease. The vaccine does not keep very well and the difference between the time of treatment needed to make the virus no longer infective and that which entirely destroys the protective power of the vaccine is not very great. This progressive deterioration of potency suggested that an efficient vaccine perhaps still contained living virus either greatly attenuated or reduced to a small fraction of the original content, but the authors believe that the vaccine probably only contains dead virus. In order to produce a lasting immunity and one which protects against all strains of the virus, it is necessary to give a dose of living virus soon after the vaccination. After such a double inoculation a solid and lasting immunity was obtained without any sign of the disease. Since immunity following the natura

[1] Jour. of Comp. Path. and Therap., 1926, xxxix., 201, 213, 222
[2] Ibid., 1928, xli., 1.

isease is life-long, it is hoped that the protection ollowing this prophylactic treatment will prove qually durable. The preparation and preservation f the vaccine still present difficulties and the need for living dose to complete the immunity is an undesir-ble complication. This is especially disconcerting ince the dose of living virus though not causing any vert symptoms of distemper has appeared in some nstances to have caused the animal to become a carrier or a time. A further paper describing the results of xperiments with dogs along similar lines is promised n the near future.

Annotations.

"Ne quid nimis."

THE AUSCULTATORY GAP.

In estimating blood pressure by the auscultatory ethod the orthodox procedure is to raise the pressure the armlet to about 200 or 250 mm. of Hg and nen allow it to fall slowly until the characteristic ounds can be heard over the brachial artery imme-ately below the point of compression. As the essure continues to fall the sounds change both quality and intensity. At first they are clear but int; later, they are accompanied by a rushing urmur; then they once more become sharp, at st increasing in intensity and then diminishing. inally, the sharp sounds are abruptly replaced by dull thud, and when the pressure has fallen another w millimetres the sounds die away. The first ppearance of the sounds marks the systolic, and the dden transition from sharp to dull sounds the astolic pressure. In most subjects the arterial unds conform fairly well to this description, and e determination of systolic and diastolic pressures easy. Sometimes, unfortunately, this is not so; e transition from the sharp sounds of the third ase to the dull sounds of the fourth phase, instead being abrupt, is gradual, and extends over a range 20 mm. or more, affording no satisfactory diastolic d-point. The determination of the systolic pressure nerally presents less difficulty, but a possible source error, first pointed out by French and American rkers some ten years ago, may occasionally lead a wrong reading. In certain cases the normal quence of the Korotkow sounds heard during compression is interrupted by a zone of complete ence. This silent interval or "auscultatory gap," it has been termed, usually replaces, in part or ole, the sounds of the second phase—i.e., those ich are accompanied by a murmur. From a agnostic point of view this is of some importance, ce it may lead to an under-estimation of the stolic pressure, the sounds preceding the auscul-ory gap being missed and their reappearance ing taken as the systolic reading. Such a mistake n easily be avoided by first estimating the systolic essure by palpation, a technique which is to be ommended, since it eliminates the necessity for mitting the patient to the needless discomfort a high initial compression when his blood pressure within normal limits.

The "auscultatory gap" was first noticed in cases aortic stenosis, but subsequent observations ve shown that it is not confined to that condition, t is frequently associated with hyperpiesis. Such s the common factor in a series of four cases ently reported in this journal by P. C. Gibson,[1] d in 28 out of 30 cases reported in America by G. Mudd and P. D. White.[2] Various hypotheses ve been put forward as to the mechanism of pro-ction of the "auscultatory gap," and an explanation its presence is to be sought in considering the ferent factors concerned in the production of the rotkow sounds. Of these the first and most obvious are rapid vibrations in the arterial wall and eddies in the blood stream. Vibrations in the arterial wall depend, first, on the tension and structure of the wall, and, secondly, on the form of the pulse-wave. The steep wave-front of the typical Corrigan pulse of aortic incompetence produces a sudden shock which excites violent vibrations in the artery, whereas the slow-rising anacrotic pulse of aortic stenosis can slip through almost unnoticed. It is like a finely tapered wedge which glides quietly and smoothly into place. The sphygmogram in hyperpiesis is not unlike that of aortic stenosis, the upstroke rising gradually to a well-sustained plateau. Consequently, in both these conditions the force acting upon the arterial wall is such as to excite but little commotion. To turn now to the second factor—the condition of the wall on which these forces act. Decompression is divisible into three stages. During the first stage the compressing pressure is considerably higher than the diastolic pressure. During the second stage it is only slightly higher, and during the third stage the compressing pressure is lower than the diastolic. It is therefore only during the third and last stage of decompression that the effective internal pressure is sufficient to keep the arterial wall on the stretch throughout the whole cardiac cycle. During the first two stages the artery collapses more or less completely in diastole. Further, during the first stage of decompression the external is so much greater than the internal pressure that the passage of the pulse-wave cannot stretch the artery sufficiently to produce violent vibrations, such as occur during the second stage, which corresponds to the maximal oscillations as recorded by Pachon's or Erlanger's instruments, and to the sharp loud third phase sounds heard on auscultation. It is easy to understand why the slow rising pulse of aortic stenosis, or of hyperpiesis, may fail to produce rapid vibrations in the artery during the earlier stages of decompression, but it is more difficult to explain why the sounds, having once made their appearance, should afterwards die away as the compressing pressure falls. The most likely explanation of this curious phenomenon appears to be that the accumulation of residual blood in the artery during the second stage of decompression acts as a damper which further limits the vibrations of the arterial wall.

RESEARCH ON POLIOMYELITIS.

In no field of medical practice is new knowledge more urgently desired than in that of the neurotropic viruses. The necessity of employing monkeys for the experimental study of these viruses has impeded progress by reason of the heavy cost involved, and although it is nearly 20 years since Landsteiner showed that the virus of poliomyelitis could be transmitted to monkeys, it is doubtful if the knowledge we have since gained of this and other neurotropic viruses has materially clarified the preventive and therapeutic outlook. On the practical side little has been discovered about the prevention and control of infantile paralysis in spite of the intensive study which has been given to the problem. The present is a favourable time for a new attack on the problem, for the last decade has witnessed considerable developments in our knowledge of virus diseases and their methods of attack. The medical profession will therefore welcome the formation of an international committee for the study of poliomyelitis under the distinguished chairmanship of Dr. William H. Park, director of the Bureau of Laboratories of the New York City Health Department. Arrangements have been made for a concerted three-year attack on the difficult problems of prevention and therapy presented by this formidable and crippling disease. To enable research to be carried out at a number of centres, both in the United States and in Europe, a sum of $250,000 has been given by Mr. Jeremiah Milbank, a prominent New York financier who takes an active personal interest in hospitals and charities. The following are the centres which have been chosen

for the proposed researches: Bureau of Laboratories, New York City Health Department, the Pathological Institutes of Columbia, Harvard, and Chicago Universities, the Pasteur Institute, Brussels, and the Lister Institute, London. As the work progresses it is hoped to enlist the coöperation of other institutions and laboratories. The various institutes are represented on the international committee by their respective heads, and the full personnel of the committee is as follows: chairman, Dr. W. H. Park; vice-chairman, Dr. J. A. Blake (New York); Drs. E. O. Jordan and Ludvig Hektoen (Chicago), Drs. F. P. Gay and Frederick Tilney (Columbia), Drs. Milton J. Rosenau and Hans Zinnser (Harvard), Dr. Lee K. Frankel (Metropolitan Life Insurance Company), Sir Charles Martin (Lister Institute, London), and Dr. Jules Bordet (Pasteur Institute, Brussels). Mr. Samuel M. Greer and Dr. Josephine N. Neal will act, respectively, as treasurer and secretary, and the committee's headquarters will be Dr. Park's office at the Bureau of Laboratories, East 16th-street, New York. Directors of research at each selected centre will be absolutely free to initiate such investigations as seem to them desirable and within the compass of their respective institutions. The results of such researches will, however, be studied and coördinated by the international committee, and will thus constitute a joint piece of work. At the Lister Institute the proposed research on poliomyelitis, for which special arrangements are being made, will be under the direction of Prof. J. C. G. Ledingham. The generosity of Mr. Milbank in making the new venture possible will be widely appreciated.

CONCOMITANT SQUINT.

In the quarter of a century that has elapsed since the publication of Claud Worth's views on squint very little has been added to our knowledge either of the causation of this condition or of the best means of treating it. Dr. Oscar Wilkinson,[1] of the Washington Eye and Ear Hospital, while fully recognising the value of Worth's work and largely quoting from his book, purports to improve upon his theory of the causation of concomitant squint. According to Worth the most important factor in the causation of concomitant squint is a congenitally defective fusion faculty. Wilkinson suggests that the weak point in this theory is that most cases of concomitant squint develop in children after they are 3 years old and have enjoyed binocular vision for two or three years. It is not so much a defect in the fusion faculty, he believes, as it is a disturbance or want of harmony in the proper uniting or coördinating of the several stimuli or retinal reflexes sent in to the centres for convergence. "The eyes are straight for three or four years and then cross. Why does fusion break down after three or four years' use?" he asks. It seems to us that this criticism of Worth's theory is hardly justified if the theory as expounded by its originator is carefully studied. The fusion faculty, according to Worth, is by no means identical with the faculty of binocular vision. The conjugation of the eyes for horizontal movement (intended to subserve the function of binocular vision) is perfected within the first few months of life. On the other hand, the power of completely fusing the two images is only gradually acquired and in the normal child is only perfected about the sixth year of his life. In the interval the coördination of the two eyes is, as it were, in a state of unstable equilibrium and may be upset by a variety of causes or a combination of causes, hereditary influence being often a marked feature. In some cases uncorrected hypermetropia is an important factor in upsetting the nervous mechanism (Donders's theory). In many cases the onset of squint occurs after whooping-cough or measles or after a severe fright which may be enough to influence this mechanism adversely in the absence of a fully developed fusion faculty. When once, however, this faculty is attained it is by itself sufficient to ensure against squint. We note that Dr. Wilkinson lays great stress on the accurate and periodical measurement of the angle of a squint. If, he says, at any age the degree of squint is not decreased after four to six months of careful attention, it becomes a case for operation. Accurate measurements for both far and near are diagnostic as to cause (anomaly of convergence or of divergence) and in operative cases determine largely the procedure to be followed. When operation is not performed Dr. Wilkinson stresses the need for constitutional treatment. "It must be admitted," he says, "that the general physical condition of the squinting child is usually far below par, and I can scarcely recall a case of squint in whom the general nervous system was even up to a low normal." The recommendations for training the fusion sense and binocular vision are largely taken from Worth with amplifications.

His views on operative treatment deserve close attention. After quoting the very divergent opinions of various authorities on the best age for operating on squint, he gives his opinion that when treatment with atropine and glasses do not markedly reduce the degree of squint within the first month they do not do so subsequently, even though they be used for years. Any child, he says, at or above the age of 5 years who is cross-eyed is a neglected child and should be relieved of its deformity. In this he differs from Worth and most authorities, who only operate early in those cases where there is a good prospect of establishing binocular vision. In those cases where the capacity for developing the fusion sense is proved to be absent, Worth prefers to wait until the child is old enough to be operated on under a local anæsthetic before correcting the deformity. As to simple tenotomy, Wilkinson agrees with all modern operators in condemning it as a routine procedure. An internal tenotomy is never justifiable in a patient under 12 years of age on account of the uncertainty of its result and the possibility of the later development of secondary divergence. He devotes much attention to advancement and resection operations, and describes his own procedure in detail. It differs from that ordinarily practised in several respects. In the first place, he attaches the cut end of the muscle tendon not to the sclera itself but to the cut scleral end of the tendon, and he therefore gets his effect not by an advancing of the place of attachment to the sclera but entirely by a shortening of the tendon. The amount of this shortening he regulates by a graduated rule by means of which he can accurately measure the length of tendon to be cut off. He recognises that the uncertainty of the amount of pull which will be exercised by the opposing muscle is liable to interfere with the result of this accurate measurement, but to counteract this he has devised a scale to test the power of the opposing muscle, and he employs what he calls a brace, the purpose of which is to put it out of action during the period of healing. With these methods of exactitude he claims to have secured good results in many hundreds of cases.

[1] Strabismus: its Etiology and Treatment. By Oscar Wilkinson, A.M., M.D., D.Sc., Surgeon-in-Chief of Washington Eye and Ear Hospital. London: Henry Kimpton. 1928. Illustrated. Pp. 240. 42s.

INNATE RESISTANCE TO TUBERCULOSIS.

Dr. C. T. Ryder, writing in the *American Review of Tuberculosis* for February, gives it as his opinion that acquired immunity plays but a small part in determining resistance to tuberculous infection which he believes to depend chiefly upon a natural innate or hereditary immunity. The tubercle bacillus, he points out, is a universal virus and most children are infected in early life. If such an infection were followed by an acquired immunity he would expect to find a high death-rate in the period of first infection, followed by a low death-rate thereafter. Thus the mortality curve for tuberculosis would resemble those of whooping-cough and measles, whereas the death-rate for the former

relatively low during the period of primary complexes and high throughout the periods in which a measure of "immunity" is supposed to have been established. The curve of the tuberculosis death-rate more closely resembles those of influenza and pneumonia, diseases which confer only a transient immunity. The high death-rate from tuberculosis in the first two years of life is attributable, Dr. Ryder considers, to an infant's "almost marsupial" dependence upon, and contact with, infectious adults. In general, he says, children of Anglo-Saxon origin have a high resistance to first infection, but tuberculosis is not one of the diseases in which infection is followed by an effective increase in resistance or security against death from the same disease in later life. The relative immunity of civilised races to the more fatal forms of tuberculosis as contrasted with savage races recently brought in contact with infection is explained by "the simple evolutionary formula of survival." A race long exposed to a disease has a much higher innate resistance to it than a race newly exposed. Dr. Ryder maintains that a first infection, even though successfully resisted, sensitises more than it protects. If a secondary infection occurs, the sensitised tissues tend to slough rapidly, and such sloughing leads to dissemination of the bacillus, especially if the lungs are affected.

MEDICAL MOVIES.

THE bulk of the subjects which are displayed by means of the cinematograph are at the best purely frivolous and at the worst degrading. But we must frankly recognise that it is only the widespread popularity of these types of demonstration that have led to the technical improvements in apparatus and methods which now make it possible to explore many problems in the medical sciences with unrivalled precision. The development of the compound microscope similarly owes a great deal to ingenious men who were more interested in seeing curious and astonishing spectacles than in the progress of natural knowledge, and Dr. R. G. Canti, whose achievements in cellular cinematography will be familiar to many of our readers, may owe more than he may suspect to Mary Pickford. We may see plainly what the movies can do for physiology if we reflect what a lot of trouble they would have saved Harvey in making out the heart beat and if we look at Marey's attempts to explain in detail how a man walks and runs with the rudimentary successive photographs which were available for him 50 years ago. It is obvious that the method is unique in enabling us to obtain a permanent record of a series of rapidly succeeding events which we may afterwards study at leisure either in sequence as individual pictures; and conversely, in demonstrating the sequence of movements and changes which extend over hours by speeding them through their stages in quick time. We can get knowledge through the cinematograph which we can get in no other way. Whether the method has any further legitimate applications in medicine is a question on which there has been some difference of opinion and practice. It is neither an excess of puritanism nor extravagant conservatism to condemn wholeheartedly the taking of films of technical medical procedures—operations, examinations, and the like—and their exhibition to lay audiences; the practice is simply indecent. And there is, and is bound to be, some doubt as to how far films should be used in educating medical students. Employed in moderation and with discretion, they can fill up some of the gaps in realism which are left by the current methods of didactic and practical instruction. But their association with picture houses makes it more necessary than ever that any miraculous and extravagant elements should be most carefully avoided; as things are, it is one of the besetting sins of the student to pay more attention to the strange and bizarre than to getting a proper understanding of the ordinary and commonplace. Those who use them or contemplate using them might also do well to reflect at length on that fine saying of Bishop Hall which should be carved over the entrance of every medical school: "God sells knowledge for sweat." For the information and instruction of medical men of more mature experience, films no doubt have a definite value of rather limited range and at the present time the most profitable field for their employment seems to be in public health propaganda among the laity. No one who saw the queues of sober men and women waiting recently to get into the venereal disease show at the lower end of Tottenham Court-road [1] or who heard accounts of what they had seen there can doubt that on the whole such exhibitions make for the advancement of good health and the promotion of good morals. Their preparation needs much care and thought. Primarily they must represent the literal truth, and though they must necessarily emphasise the points they want to make they must be purged of the miraculous and extravagant; no one is quicker to detect an unreal exaggeration of technical matter than an audience of lay people. The precise mode of presentation must be left to experience and the experts. Few films of which healthiness is the main topic can possibly run for two or three hours; medical matters might appear as subsidiary sections much in the same way as the topical pictures of current events or perhaps better still as bye points in an ordinary tale; Charlie Chaplin could do as much with "drink more milk" as with any other slogan.

TERMINAL DISINFECTION.

SLOWLY but surely a conviction is growing among medical officers of health and general physicians that the traditional methods of disinfection require revision. The early discoveries in bacteriology were the foundation of a general belief in the survival of disease germs on fomites, and the attempt to disinfect places and inanimate objects which have been in contact with patients has been one of the chief preoccupations and channels of expenditure of public health authorities all over the world. The reaction against this indiscriminate and costly industry has been fostered by new discoveries in epidemiological and bacteriological research, and perhaps even more by a realisation that the risk of contamination of surgical wounds by any object not brought directly within the field of operation is negligible. The most notable contribution to the subject within recent years is undoubtedly the monograph "On the Practice of Terminal Disinfection," published by Prof. C. Chagas, Director-General of Public Hygiene of Brazil, in the *Bulletin Mensuel d'Hygiène Publique*, for May, 1926. This paper, on which we commented a year ago,[2] translated into English, is now published as a separate pamphlet,[3] and should be read by every medical man who is in any way connected with the struggle against infectious illness.

Prof. Chagas's theme is that terminal disinfection, as practised in most countries, "is a procedure erroneously founded, almost always useless, and whose practical results bear no adequate relation to the labour and the cost involved." His main objection to it is the impossibility of finding the germs which it is desired to kill, and the consequent necessity of blindly and wastefully disinfecting the whole of the premises under suspicion. The solutions leave untouched numberless crannies in which germs may survive. Experiments, of which he quotes Flügge's, have shown that cleansing operations far more rigorous than are ever used in ordinary practice cannot destroy all the organisms in cultures placed on walls and floors, and that ordinary antiseptics require an enormously longer time to act effectively on infective material than they are ever allowed. Fumigation has been described by Dr. Andrew Balfour on unimpeachable evidence as "undoubtedly a process of camouflage." To modify the current methods by increasing the strength or prolonging

[1] See annotation in THE LANCET, Feb. 4th, p. 247.
[2] THE LANCET, 1926, ii., 610.
[3] William Hodge and Co., Ltd., Glasgow. 1928. Pp. 45. 2*s*. 6*d*.

the application of the disinfectants would be impracticable on many grounds. The testimony in favour of these arguments is so strong that few well-informed persons will venture to doubt them. But, as Dr. Chagas points out, the real objection is not so much in the technical uselessness of terminal disinfection as in the fact that it is terminal at all. The channels by which infection is disseminated are not the surroundings of the patient, but his excreta, including sputum. By the time the sanitary corps arrives the harm has been done; outside persons have been infected, and a large proportion of them have commenced a busy and destructive career as carriers.

Finally, the part that terminal disinfection plays in allaying public anxiety unjustifiably is almost as deleterious as any of its other evils. The knowledge that a ritual which will clear up all trace of the disease is to be performed at its end undoubtedly leads to the neglect of just those simple precautions which, taken during the course of the illness, would do away with even the hypothetical need for terminal disinfection. Given efficient "current disinfection"—i.e., the sterilisation of all articles soiled by the patient's excreta and the prompt disposal of the excreta themselves—very little remains to be done. The kind of terminal disinfection recommended by Prof. Chagas consists of the cleansing, by ordinary physical or chemical means, of articles that have been in direct and recent contact with the patient; the disinfection of obviously contaminated objects; the vigorous use of soap and water, and the liberal application to the sick-room of sun and fresh air. Even this is largely superfluous, he says, when current disinfection has been properly carried out, and he goes on to prove the uselessness of terminal disinfection for each of the common epidemic diseases separately.

MOSQUITO-PROOFING IN INDIA.

IT only needs a rough computation to indicate what is the loss to the Army in India from insect bites. In 1926 sickness in hospital accounted for 660,000 working days or an average of 11½ days per man. Of these admissions a quarter were for venereal disease, a twelfth for injuries. Of the remaining two-thirds a quarter, (say) 110,000 days, were attributed to the attacks of biting insects—mosquitoes carrying dengue and malaria, sandflies with their own special infection, and others (culicidæ, for example) to which the Army Health Report for that year ascribes "much of the inflammation of areolar tissue." It may therefore be said without exaggeration that 20 per cent. or more of all the illnesses that come to attack our soldiers in India can in peace-time be prevented if we effectively protect them from the assaults of insects. and it is this realisation no doubt which is reflected in the increasing interest taken in mosquito-proofing of barracks and hospitals.[1] If all openings are covered carefully by an expert with copper gauze, this affords complete protection against insects of all kinds—flying beetles, and culicidæ as well as anopheles; the rooms are cooler, and as mosquito nets are unnecessary the men get more good of the punkahs and sleep better. The method is not novel; mosquito-proofing of houses is an old and well-known story in the Roman Campagna, and at Panama; it was the final act in the extinction of malaria during the late war in the large rest camp at Taranto in the hands of the late Colonel J. C. Robertson, I.M.S.[2] Hygiene makes slower progress perhaps in India than elsewhere, but in 1925–26 mosquito-proofing was tried at Lahore, the most highly malarious of all the large stations, with results as striking as could be wished. From August to October, 1926 (the malarial season) 500 men in unprotected barracks had a hospital admission-rate for malaria of 47 per 100, while 300 men in mosquito-proofed barracks had a rate of only 18 per 100, or a saving of 89 cases. Taking the average stay in hospital of malaria cases at 8·8 days, this means some 800 days of illness avoided, disregarding unrecorded periods of light duty and convalescence. Added to the general knowledge we have of malarial prophylaxis elsewhere these figures appear to be decisive, and would justify the instalment of screen protection all over India beginning with stations of high malarial incidence (say) over 150 per 1000. If it be contended that the cost is high, so also is the cost to the State of the British soldier in India, and this cost is rising while the medical service is diminishing. The rubber growers of Malaya have found that sanitation pays and Sir Malcolm Watson has told us that the £4 per coolie spent on malaria prevention has had an immediate return. The United States spent £20 to £700 per sq. mile in the war on the protection of their home camps against malaria. In Palestine the Army spent 12*s*. per man (£40,000 in all) on malaria protection of the troops to prevent Lord Allenby's forces from melting away before his break-through. What value, it may well be asked, have the 800 working days saved to 300 men of the garrison of Lahore by mosquito-proofing? Nor does the benefit end there, for we have to take into account also the fewer carriers of gametes in barracks to infect later broods of anopheles, and so in their turn other human victims. The 90 cases saved would have each required at least an ounce of quinine, a total saving of some £9 among 300 soldiers. And in 1926 there were in India 56,000 soldiers not counting officers and their families.

[2] THE LANCET, 1920, ii., 30.

CIRRHOSIS OF THE LIVER.

MODERN pathology would assume, in the absence of very definite evidence to the contrary, that the increase of fibrous tissue in ordinary portal cirrhosis is a replacement fibrosis—that is, that the growth of connective tissue is not the primary change, but follows a destruction of the parenchyma of the liver. The difficulty of this view has been that degeneration limited to the peripheral parts of the lobules is very seldom seen in human post-mortem material; it turns up now and again, but cannot be associated with any particular precedents except possibly pneumococcal peritonitis. Most of the poisons which affect the liver destroy the central zone of the lobule (e.g., phosphorus, chloroform, deficiency of oxygen, jaundice), and the bacterial focal necroses (e.g., typhoid fever) are scattered irregularly without any definite zonal distribution. Prof. F. B, Mallory has endeavoured in recent years to connect chronic copper poisoning with liver cirrhosis, and it is just possible that the recent decline in the frequency of the disease is due as much to giving up copper cooking vessels as to moderation in alcohol. But experiments with manganese have given more suggestive results. Dr. G. M. Findlay showed that manganese caused hepatic cirrhosis in rabbits, guinea-pigs, and rats, and his experiments have now been confirmed and elaborated by Drs. E. W. and P. E. Hurst.[2] It is quite clear from their results that manganese salts give the necrosis required on a priori grounds, which is limited to the peripheral of the lobules, and that this is followed by a reparative fibrosis which ultimately gives a condition quite like human cirrhosis. Control experiments with chloroform and phenylhydrazine, which cause necrosis of the central zone of the lobule, very rarely showed any cirrhosis. The interesting observation is also recorded that the cirrhosing effects of manganese are greatly enhanced by repeated intravenous injections of living *colon bacilli*, recalling Adami's work on the relation of chronic bacterial infection to the disease. Whether manganese can reasonably be implicated as a cause of human cirrhosis is uncertain. Industrial manganese poisoning gives rise to nervous symptoms resembling paralysis agitans and to emotional disturbances; experience at autopsy is inadequate to show whether

[1] Brit. Jour. Exp. Path., 1924, v., 92.

[2] Jour. of Path. and Bact., 1928, xxxi., 306.

he hepatic cirrhosis which has been found once is requent or usual. It is a widely distributed element nd few samples of the surface of the earth and the hings which are on it will fail to show some evidence f its presence. There is, however, very little in the issues of birds and mammals (though they must often ake in considerable quantities in their food) or in uickly growing plants such as cabbages or cereals; omestically there is no particular and general use for he metal or its salts and even permanganate as a isinfectant is rarer than it used to be. It is difficult o see how man would in these ways come into intimate ontact with any but traces of manganese. On the ther hand, it accumulates to a remarkable degree in he leaves of some trees and in some invertebrates, otably slugs and mussels, and it seems to be worth hile to analyse some of the bypaths of human food, specially the tasty additaments which are supposed to imulate an appetite in the chronic gastritis of lcoholism.

THE COLOUR OF THE SKIN.

In connexion with phototherapy a good deal of ork has been done on the absorption of ultra-violet ght by the skin, but the general question of the eflecting and absorbing powers of the skin for light f different colours has received little attention. Not uch has been found out about the differences in is respect between the skins of different races, and paper on this subject by Mr. J. H. Shaxby, D.Sc., and r. H. E. Bonnell in the April issue of *Man* forms an portant contribution to the literature. They used photometric method in which the skin is illuminated d the amount of light which it reflects is compared ith the amount reflected by a standard matt white rface of the same area. Successive observations ere made with white, red, and green light, first with given area of skin and then with the standard matt hite surface. The ratio of the various readings btained with a given colour gives the reflecting wer, or the reflection-coefficient, of the skin for this lour. The reflecting power of human skin was easured for about 270 subjects, European and gro, the Europeans being mostly Welsh or English. addition reflection-coefficients were found for fferent parts of the body. It was found that when hite light is used the parts of the body arranged in der of increasing power of reflection are, for uropeans, the palm, back of the hand, forehead, eek, outer side of the arm, and inner side of the m. For negroes the corresponding order is the back the hand, forehead, outer side of the arm, cheek, ner side of the arm, and palm. The ratio of the flection-coefficients of negro to European skin are ughly 60 per cent. for the palm and 30 to 40 per cent. the other regions examined. The variations with een light run almost parallel to those found with hite light. For red light the tendency seems to be the fairer subjects to show relatively less reflecting wer—that is, the swarthier skin is also slightly the lder skin. Relative ruddiness of tint is measured the ratio of the red to the green light coefficient and termed "red-green ratio." Records of reflection the cheek show that a negro may be ruddy or llid within about the same limits as a European. . Shaxby and Mr. Bonnell conclude from their periments that there seems to be no essential ference in type between the reflection of white and oured skins, negroes in this respect differing from ropeans only in the amount of melanin pigment in e skin.

As we have already announced, a conference rheumatic diseases will be held at Bath on y 11th and 12th under the presidency of Sir George wman. The three sections will be devoted to cial Aspects, Causation, and Treatment, and a ge number of papers will be read concerning the ute rheumatism of childhood and also the various ms of arthritis and fibrositis affecting older patients. dical questions in connexion with the conference uld be referred to the hon. medical secretary, Dr. Vincent Coates, at 10, The Circus, Bath, whilst copies of the full and interesting programme may be had from the hon. organising secretary, Mr. John Hatton, at the Pump Room, who will also make arrangements for railway vouchers and hotel accommodation.

THE Croonian Lecture of the Royal Society will be delivered at Burlington House, on Thursday, May 10th, at 4.30 P.M., by Prof. Ivan Pavlov, of Petrograd. The subject will be Some Problems of the Physiology of the Cerebral Hemispheres. Prof. Pavlov, who is a Foreign Member of the Society, paid his last visit to this country in the summer of 1923, shortly before the publication of his classical treatise on conditioned reflexes.

THE death is announced of Dr. Reginald Spencer Pearson at the age of 62. Dr. Pearson was Mayor of Lambeth last year.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXIV.—TREATMENT OF RICKETS.

I.—PROPHYLACTIC MEASURES.

THE prevalence of rickets in London and probably throughout Great Britain has been greatly diminished during the last few years, but the present position cannot be regarded with complacency. The means for eliminating all but the slightest manifestations of this disease are readily available, yet efficient prophylaxis is very often omitted even when infants are under medical supervision. The following figures show the wide prevalence of rickets of a grade which is radiographically recognisable—the true incidence would be higher than the figures suggest as changes may be present in the bones of the head and the thorax before they are apparent at the wrist. Of 167 unselected infants of from 1 week to 2 years old seen in the out-patient department of the Queen's Hospital for Children in April, 1925, 8 per cent. had radiographic evidence of rickets, the percentage rising to 15 if only those aged from 4 to 13 months are included. This series did not include cases sent to hospital for rickets, and the disease appears to be much commoner in many parts of the British Isles than it is in London.

Diagnosis.

The basis of diagnosis differs widely, but since more efficient treatment is closely connected with better diagnosis I would suggest that, where radiographic and chemical findings are not available, diagnosis should be based only on clinical evidence of *changes in the bones* and not upon head-sweating, pallor, late dentition, flabby muscles, pot-belly, or an excessive deposition of fat, all of which are often found in non-rachitic infants.

The early bone changes require careful and systematic examination for their discovery. Among the most useful are: craniotabes, enlarged rosary, and enlarged epiphyses. During the second six months of life an enlarged rosary is probably the most valuable early sign, but in an infant aged 4 to 7 months craniotabes, developing behind the ears, is often one of the earliest signs, and craniotabes is the only conclusive clinical sign of *active* rickets which we possess. As soon as the process of "healing" begins—i.e., as soon as normal calcium deposition is re-established—calcification of the soft areas in the skull is increased, and craniotabes has usually completely disappeared within four weeks of the beginning of efficient treatment. Craniotabes, however, is rarely found in London after 9 to 10 months of age, and, in its absence, although a guess may be made as to whether the disease is active, healing, or healed—from such factors

as the child's age, duration of treatment or season—yet the precise stage of the disease can only be accurately determined by one or more X ray photographs or by chemical examination of the blood.

Prophylaxis.

In considering prophylaxis one must constantly bear in mind the cause of the disease, and its seasonal and age incidence. In London it is comparatively rare to find cases of active rickets in the late summer. The disease develops during the winter, probably reaches its maximum incidence in April, and the great majority of cases heal in the course of the summer, though they may relapse in the following winter. In artificially fed children not receiving specific antirachitic treatment, *the deciding factor in the development of rickets is usually the amount of exposure to light, and this is determined primarily by season and by the amount of time the infant spends out of doors.* Some breast-fed infants, who have little outdoor life, also develop rickets. It must be remembered that both human milk and cow's milk are relatively poor sources of vitamin D (the antirachitic vitamin) and throughout the winter every artificially fed infant and those breast-fed infants who may not get sufficient outdoor life daily should receive special preventive treatment. During the summer, if the child is out daily, special treatment is generally unnecessary. In the latitude of Toronto it has been found that in April and May the sun's rays have about eight times the antirachitic value that they have in December, January, and February, and it is from the autumn until April that specific prophylaxis is required as a routine measure.

The great majority of cases of rickets begin during the first year of life, probably most often between 4 and 10 months of age, and consequently it is for children during the first year that prophylaxis is particularly needed, though it is desirable to give such special treatment during the winter to "toddlers" also. Since premature babies are specially liable to rickets, which frequently develops before 5 months of age, special treatment should whenever possible be given to these infants from 1 month old whether they are breast-fed or bottle-fed, and usually in summer as well as in winter. The susceptibility to rickets of Italian and of negro babies in this country and the United States has often been noted, and specific treatment throughout the year is advisable for infants whose forbears lived in more sunny latitudes than our own.

General measures of prophylaxis are: (1) The procuring by all possible means of adequate outdoor life daily for infants throughout the year, and not only in fine weather; and the exposure of the child, so far as possible, to what sunlight is available. The mother should be persuaded to keep the child out of doors daily during the hours of light, and whenever possible with the hood of the perambulator down. (2) The encouragement of breast feeding. (3) The inclusion in the ordinary diet of infants and children not on the breast of an adequate amount for their age of those foodstuffs containing vitamin D—e.g., milk, eggs, and meat.

Specific treatment may be given either by supplying a substance rich in vitamin D by mouth—e.g., in the form of cod-liver oil—or by exposing the child to an artificial source of ultra-violet light and so bringing about the formation of vitamin D in the body. In either case the action of vitamin D appears to be identical, and to supply it by mouth is simpler and more economical in time and money. There are, of course, a very small proportion of infants—e.g., premature infants with poor digestive power—to whom it may be possible to give light therapy when cod-liver oil cannot be tolerated. The question arises whether artificial light therapy has any beneficial effect on the general health, other than that due to its power of forming vitamin D in the skin, which renders it more desirable than cod-liver oil as a routine prophylactic measure for infants. I have been unable to demonstrate any significant difference in rate of growth, hæmoglobin content of the blood, or liability to intercurrent illness between a group of infants getting light therapy as well as cod-liver oil and another group treated with cod-liver oil alone. I therefore consider that in the present state of our knowledge administration of cod-liver oil should be the routine method of prophylaxis. No method has been shown to prevent completely all manifestations of rickets in every case, but with proper cod-liver oil treatment, though slight craniotabes or costochondral enlargement may appear, changes of a grade radiographically recognisable are, in my experience, banished.

The antirachitic value of different specimens of cod-liver oil varies widely, but half a drachm of a 50 per cent. emulsion of most oils given three times daily is an adequate dose. To bottle-fed babies it is best given in the feed. Nearly all infants from the first weeks of life will tolerate it satisfactorily if the emulsion is started a few drops at a time, and increased to half a drachm three times daily within 4 to 14 days. Large doses may cause digestive disturbances and do not appear to have any compensating advantage. After infancy many children prefer the taste of cod-liver oil and malt, half a drachm of a good preparation three times daily being generally adequate for children over 12 months.

Certain concentrated forms of vitamin D are now on the market—both extracts of cod-liver oil, and also ergosterol activated by irradiation. It is probable that in the future some such preparation will have a wide field of usefulness, but the correct dosage and the keeping properties of these preparations need careful investigation before they are used on a wide scale. An effective curative dose of irradiated ergosterol mentioned in the last report of the Medical Research Council is apparently equivalent in vitamin D content to nearly half a litre of cod-liver oil daily. Surely we need to be very certain that over-dosage has no ill-effects on children before such preparations are widely used. Moreover, if the keeping property of some of these preparations proves to be poor, one may be quite unaware whether one is using an extremely potent or a totally ineffectual drug. It seems to me far preferable to use cod-liver oil of a good brand rather than proprietary preparations of unknown vitamin-D content. The use of ineffectual substitutes is certainly responsible for the development of many cases of rickets. Many manufacturers are now taking advantage of the facilities offered by the laboratories of the Pharmaceutical Society of Great Britain, where tests as to vitamin content can be performed, and it is possible that in the near future dosage will be on a proper quantitative basis.

Summary.

General prophylaxis is best attained by as much outdoor life as possible throughout the year.

Cod-liver oil emulsion, or cod-liver oil and malt for older children, is advocated for routine specific prophylaxis. They should be begun gradually. Proprietary preparations of unknown antirachitic value should be avoided.

Specific prophylactic treatment should be given to—

(*a*) All artificially fed infants throughout the winter, and throughout the year if sufficient outdoor life cannot be ensured.

(*b*) Breast-fed infants who are little out of doors.

(*c*) All premature infants throughout the year.

(*d*) All infants of dark-skinned races living in this country—throughout the year.

Physician to the Queen's Hospital for Children.

MOORFIELDS EYE HOSPITAL.—The annual report of the Royal London Ophthalmic Hospital records the inauguration of a properly equipped ultra-violet ray department which has already "more than fulfilled expectations," 206 patients having made 3765 attendances in little more than ten months. The committee of management contemplate increasing the general ward accommodation from 120 to 130 beds, providing rooms for 21 nurses, and 15 private rooms for paying patients. These extensions will cost £28,000.

THROUGH YUGOSLAVIA.

A visit was made during three strenuous weeks of April by a party of English men and women interested n Yugoslavia, its racial make-up, its chances of ıational development, its scenery and amenities, and, or the medical members of the party especially, the neasures taken by the new kingdom to promote ublic health. A note upon this aspect of the tour vill be of interest to the profession.

The Territory of the South Slavs.

Not everyone is quite clear as to the significance of he title Yugoslavia, a title which it may be said is tself a sort of compromise, offending no one, whereas he adoption, for the combination, of the name of ny one of the constituent races might have been nfortunate. The title means the South Slavs, and heir country onsists of our princi- al divisions. irst there re the Slov- nes, the old lav race, ith its apital at jubljana, hich has een for long close asso- ation with ıe Austrian mpire, ıaring its ltural de- elopment ıditscatho- religion. econdly we ave the roats, rep- sentatives of the ancient and once powerful Slav ngdom whose crown was joined to that of Hungary 1901; the capital is at Zagreb[1] (previously nown as Agram) and the large Croat territory resents great differences of development in civil- ation. Roughly speaking the north, having me strongly under Austrian influence, is com- aratively advanced, while the south bears the haracter of a poor agricultural race, struggling in any places with unpromising soil, despite its tracts fertility and still retaining many traces of Ottoman le. East and south of Croatia we have Serbia, far the largest Slav race contributing to the new nalgamation, a fact which has produced the difficulty patriotic breasts of distinguishing between a n-Slavia and a pan-Serbia. The Serbs as a whole e not so cultured as the Slovenes and northern oats, but their development under the racial dependence ensured to them by the establishment of e kingdom of Serbia with its capital at Belgrade has en freer. Bordered on the north by Austria and the east by Roumania and Bulgaria, while faced the west by the Adriatic shore of Italy, the ographical position of Serbia brought about its litical circumstances and made of the Serbians a eat race of soldiers. Below Serbia proper come the ovinces of Bosnia and Herzegovina, where the rk ruled for nearly five centuries until Austria inter- ned in her much criticised manner; here we have ded to the complications produced by the existence both the Roman Catholic and the Orthodox or Greek church a large proportion of Mahometans. Finally, along the south-west of the new kingdom runs the narrow strip of Dalmatia with its rocky coast and valuable harbours, below which lies little Montenegro separated from Greece by Albania.

For the ethnological student, therefore, a curious field of investigation is displayed. For the various Slav races, possessing and practising four religions—inasmuch as to the Catholic, the Orthodox, and the Mahometan, we must add in many districts a large proportion of Jews—inhabit territories which vary from the most fertile meadows to the most sterile rocks, and inherit ideals of political and social life which are allied on the one side to those of an ancient and cultivated European court and on the other side to the rudimentary schemes of existence satisfactory only to the most backward peoples.

Such in outline is the new kingdom which those who direct the fortunes of Yugoslavia are seeking to weld, as best they may, into a symmetrical and homogeneous entity, so that it may play its part as a nation among other nations. Neither history nor geography pretends to be other than the briefest summary, useful for understanding some of the main conditions of life in Yugoslavia as a whole. And once again medicine, preventive and curative, is proving itself the grand direction in which efforts can be made for the benefit of all, whatever their religion, their history, or their environment. The diseases will vary in such varying circumstances as those of Yugoslavia, but the desire to be protected or relieved is common, and indicates a prime direction in which the Government can advance the interest of its dependents.

Health Organisation in Yugoslavia.

The organisation of the public health services in the Kingdom of the Serbs, Croats, and Slovenes has been well described in a publication of the League of Nations by Dr. A. Štampar, head of the Health Section of the Ministry of Public Health at Belgrade. The monograph was reviewed in our columns on its appearance alongside of the similar memoranda emanating from other States, so that it is possible that the general design in Yugoslavia is familiar to some of our readers. Since the kingdom was proclaimed—namely, at the end of 1918—a Ministry of Public Health has been created, and to this bureau there was soon added a Ministry having the care of social institutions. When two years later the real constitution of the country came into being, the Government was placed in the possession of legislation dealing with public health in a general manner, taking the supervision of labour and the improvement of general and social hygiene upon its own shoulders, and recognising special responsibilities in such vital matters as the assistance of motherhood and childhood, the material care of workers in illness or disablement, the provision of free medical attention for the poor, and the investigation of the causes of disease. All these duties are assumed, and are being carried out, by the Government with as much activity

[1] Cities in Yugoslavia often possess two names, that which y bore under Austro-Hungarian rule and the older name to ich they desire to revert.

as possible in a land where practical measures must often be attended with difficulty, owing to deficient intercommunication, diversity of religions, and widespread illiteracy.

The duties of the Ministry of Public Health may be summarised as follows: To promote the regular increase of the population by encouraging parenthood and healthy childhood; to protect public health by the establishment of institutions for the treatment of disease and for the study of its prevention; to supervise the health of the nation by watching the incidence of disease; and to educate the people in health matters. As a first weapon in the contest, the kingdom possesses three faculties of medicine, one at Zagreb, one at Belgrade, and one at Ljubljana, the last being of recent formation. Through these faculties special health staffs can be trained and there are training colleges for nurses allied to them, while behind them are two great institutes for social medicine—one at Belgrade and one at Zagreb. The programme at each of these institutions is identical, and the English visitors were given the opportunity of thoroughly inspecting the institute at Zagreb.

The Institute of Hygiene and School of Sanitation at Zagreb. (Fig. 1.)

The School may be said to owe its origin to the veteran Prof. Milan Yovanovich Batut, who preached at ancient Agram the doctrines of public health throughout his long life, and who lived to see many of his ideals realised in the Zagreb Institute. The School was erected with the aid of the Rockefeller Foundation and is combined with the National Bureau of Hygiene at Zagreb into one Institution. Its functions, according to statutory regulations, are much what might be expected from the list of responsibilities, detailed above, which are undertaken by the Ministry of Health. The specified duties are as follows:—

(*a*) To help all persons wishing to get acquainted with problems of public health, in receiving a special education, by founding of libraries and museums, by arranging for lectures and suitable courses, by publishing books and pamphlets, and through any other suitable means.

(*b*) To organise special courses for various professions where education and instruction may be imparted in all branches of public health.

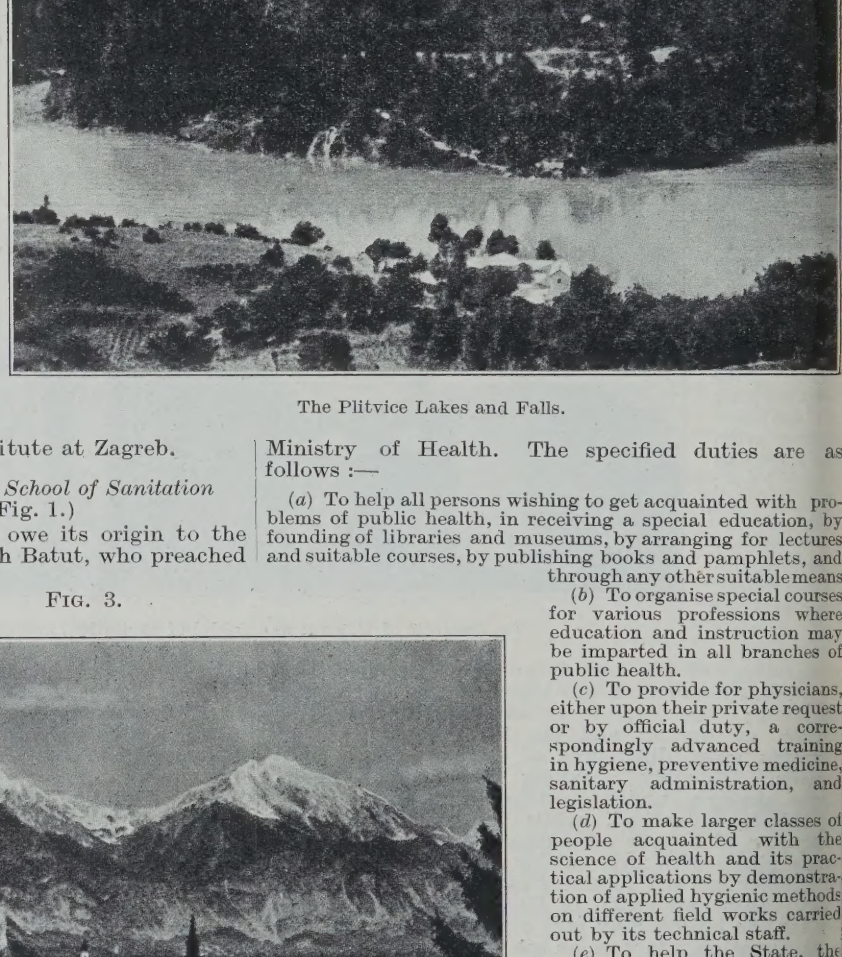
(*c*) To provide for physicians, either upon their private request or by official duty, a correspondingly advanced training in hygiene, preventive medicine, sanitary administration, and legislation.

(*d*) To make larger classes of people acquainted with the science of health and its practical applications by demonstration of applied hygienic methods on different field works carried out by its technical staff.

(*e*) To help the State, the self-governing public bodies and private institutions as well as individuals in their efforts to carry out all projects bearing upon the improvement of public health in a more reasonable and efficient way, by giving expert opinions and instructions, and by elaborating projects in all questions pertaining to public health.

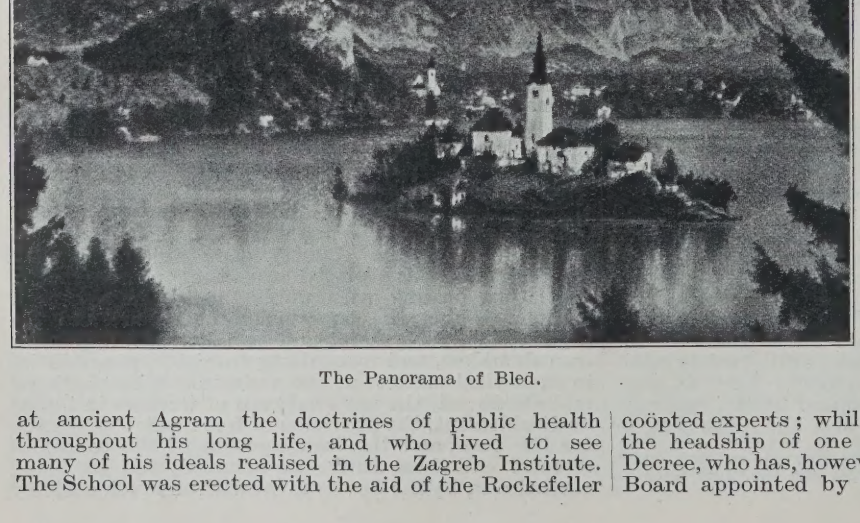
Further, the School issues certificates of attendance upon lectures given by approved teachers, being either professors at the Institute or the University, or coöpted experts; while the whole organisation is under the headship of one Director, appointed by Royal Decree, who has, however, the assistance of an Advisory Board appointed by the Minister of Public Health.

FIG. 2.



The Plitvice Lakes and Falls.

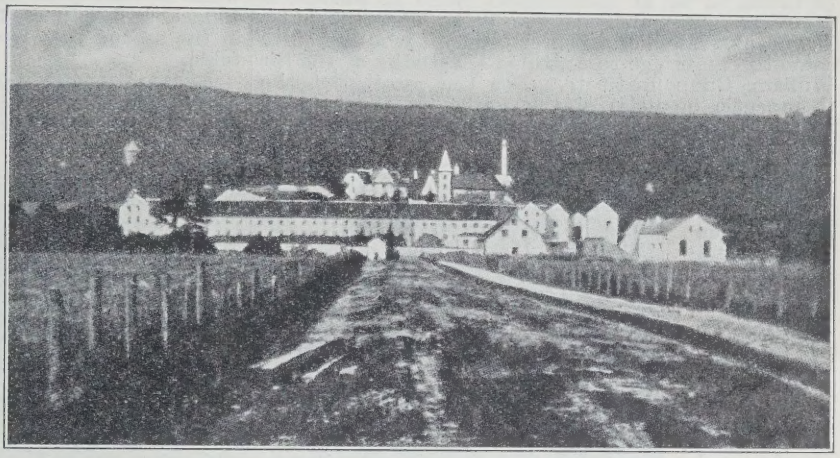
FIG. 3.



The Panorama of Bled.

This Board consists of some 30 persons representing the views and claims not only of all Government educational and civic bodies, but also the Red Cross Association and the Yugoslav press; but as the Board holds only two ordinary meetings yearly it is clear that the Director can act in most cases independently. He has, however, to consult the Board in respect of his budget and his choice of staff, while he can submit any question to them, and they can at any time make suggestions to him as to policy. It is well that finance comes under the inspection of this widely representative body, for the sources of income of the Institution are many and consequently many are directly interested in learning how the funds are spent. Not only does the State make a grant, while public bodies and many associations and individuals subscribe, but the School itself makes collections for special purposes, and fees for tuition and admission to lectures and laboratories have to be accounted for, as well as the sales of laboratory production.

FIG. 4.



The Trappist Monastery at Banjaluka.

The Regulations of the Institute of Hygiene.

Regulations for the Institute are as carefully thought out as those for conducting the School, and were it not for the certainty that with developing activities they are sure to become modified we should get the impression that they are too detailed. In Great Britain things are done first, as they are needed, and rules are made later for carrying on and for future expansion—sometimes as they are needed and not infrequently when they are long overdue; so the succession to an elaborate organisation, derived from more advanced countries, presents a curious picture; we feel at the same time that, while the new civilisation is starting with a great number of problems already solved, it is impossible not to apprehend that there is a risk of superficiality, the results of work done elsewhere being accepted without any period of personal trial. In Yugoslavia, as regards preventive medicine, this risk is being provided against by the intention to carry on fundamental work through their own men, but with close attention, especially by communication with the League of Nations, to what is being done in other countries.

The Institute of Hygiene with the School of Public Health will have the following departments eventually, and much of the work is already started: (1) administrative; (2) bacteriological-epidemiological; (3) for the preparation of biological products; (4) chemical, with the duty of controlling foodstuffs; (5) an antirabies bureau; (6) a bureau for the preparation of small-pox vaccine; (7) a hospital for contagious diseases; (8) a department of parasitology; (9) a section of rural sanitation and sanitary engineering; and lastly (10) a department of social medicine where hygienic propaganda are considered and the study is undertaken of national pathology and vital statistics.

FIG. 5.

The Market, Serajevo.

The work falling under the various sections can be coördinated by the central character of the Institute, and, where it is proceeding, is following the pattern of similar work done in this country, with the full advantages of an excellent equipment. Special attention may be called to the work in connexion with rabies, for the work proceeding in this department implies a rising prevalence of the disease. The department appeared to be busy in diagnosing the presence of rabies in suspected animals, in arranging for the immunising on the spot of persons already bitten, and in preparing and distributing the vaccine. The Fourth Epidemiological Report of the Health Section of the League of Nations gives the figures for human rabies in Yugoslavia in 1925 and 1926 as follows: 1925, 14 cases with 14 deaths; and 1926 28 cases with 25 deaths. These are the latest figures published, and at the Institute there seemed to be ground for believing that the rise in the disease was being maintained.

The evolution of spas and health resorts also comes

under the notice of the Institute. As yet not many centres have been developed and the possibilities of this sort are only now receiving attention. The visitors from this land were able to see the careful manner in which the medicinal qualities of the natural waters of Yugoslavia are being investigated as an analysis was being conducted of the mineral waters of Liphik, in a Slavonian valley, whose make-up promises to be of considerable value in rheumatic disorders. The analysis was being undertaken by Dr. Stanko Miholic, a Zagreb student, who has since come to Cambridge to continue his studies at the Sir William Dunn Institute. For the most part the therapeutic qualities of the waters of the country remain as yet undeveloped, but balneology is represented by beautiful health resorts such as Plitvice (Fig. 2) and Bled (Fig. 3).

FIG. 6.

Protestanska Crkva, Serajevo.

The Incidence of Disease in Yugoslavia.

The Kingdom of the Serbs, Croats, and Slovenes is subject to the six great infectious diseases which are found throughout Europe—namely, small-pox, typhoid, typhus, dysentery, scarlet fever, and diphtheria; here the figures available for the six years 1919–24 inclusive show that already immense improvement has followed under the efforts to meet the circumstances in a scientific manner, such as have been detailed. How thorough the attempt at notification of disease is may be judged by the fact that it is a public duty to send a telegram direct to the Ministry of Health when the presence of a serious epidemic has been verified by diagnosis supported by laboratory tests. All these six diseases must be notified to the health authorities at once, who send their reports to the Ministry on the 7th, 14th, 21st, and *last* day of every month, the fixed dates facilitating comparisons between various months.

Infectious Diseases in the Kingdom of the Serbs, Croats, and Slovenes.

Number of inhabitants 12,017,323.

Diseases.	1919.					1924.				
	Morbidity.		Mortality.		Case mortality (per cent.).	Morbidity.		Mortality.		Case mortality (per cent.).
	A.F.	Per 100,000.	A.F.	Per 100,000.		A.F.	Per 100,000.	A.F.	Per 100,000.	
Small-pox	5,278	43·4	1100	9·2	20·8	308	2·6	62	0·51	20·1
Typhoid fever	3,969	33·0	579	4·8	14·6	1051	8·8	153	1·3	14·6
Typhus ..	12,198	101·4	1499	12·5	12·3	232	1·9	14	0·12	6·8
Dysentery	17,532	141·5	3100	73·5	17·6	209	1·7	18	0·15	8·6
Scarlet fever	1,521	12·7	224	1·9	14·7	4478	37·3	908	7·6	20·3
Diphtheria	1,406	11·7	126	1·1	9·0	700	5·8	118	0·98	16·9

A.F. = Absolute figures.

Estimating the number of inhabitants at 12 million, the interesting comparison comes out that in 1919 there were over 5000 cases of small-pox and in 1923 there were 1000, and in 1919 12,000 cases of typhus, while in 1923 there were only 1000, the mortality per 100,000 falling in the first case from 9·15 to 0·51, and in the second case from 12·47 to 0·12. (See annexed table.

A large proportion of the rest of the sickness of the country is comprised as might be expected in the sufferers from malaria, tuberculosis, and venereal disease, and vigorous campaigns have been initiated in each case.

Malaria.—Yugoslavia is one of the most malarial countries in Europe. It is possible that in certain parts of the kingdom, especially in the south, from 8 to 9 per cent. of the inhabitants are actually suffering, and the number of cases and the material loss entailed have made the check of malaria one of the most anxious problems before the Government. Austria had taken some steps to check malaria before the war, especially in Dalmatia, and during the war antimalarial measures were taken in the French and British lines which have borne fruit since. In 1923 an antimalarial campaign was undertaken at various epidemiological and bacteriological stations, of which the chief one is situated at Trogir, on the Dalmatian coast and famous for its magnificent church. At these stations attempts have been made to collect in an orderly manner material information as to the distribution of malaria, while to a new institute at Skoplje will be left the central organisation of the whole work. Eventually 50 auxiliary stations will be engaged on a simultaneous campaign under the direction of specialists, the laboratory investigations necessitated being undertaken at Belgrade.

Tuberculosis.—The campaign against tuberculosis is not so far advanced, nor is the disease so rife, though its incidence amongst the Mussulman population is heavy owing to the confinement of the women and children to the harems. The considerable Jew population appears to be the least vulnerable in this respect. As might be expected, southern Serbia and Montenegro suffer principally, while Slovenia and Dalmatia, which is comprised in a western sea-coast, are the most free. A sum approximate to £75,000 is being spent on the erection of anti-tuberculous dispensaries, of which 30 exist, while there are upwards of 1000 beds for tuberculous subjects scattered in various sanatoriums and isolation hospitals.

Venereal Disease.—Antivenereal dispensaries have been established by the Government where cases of venereal disease which have been sought out are

reated gratuitously, while reliance is here much put pon the distribution of pamphlets and explanatory otices. But the illiteracy of the countryside has to e combated, and flamboyant use is being made of the heatre, the cinema, the museums, and exhibitions, hile illustrated posters give lessons of warning of an nmistakable sort.

The Medley of Yugoslavia.

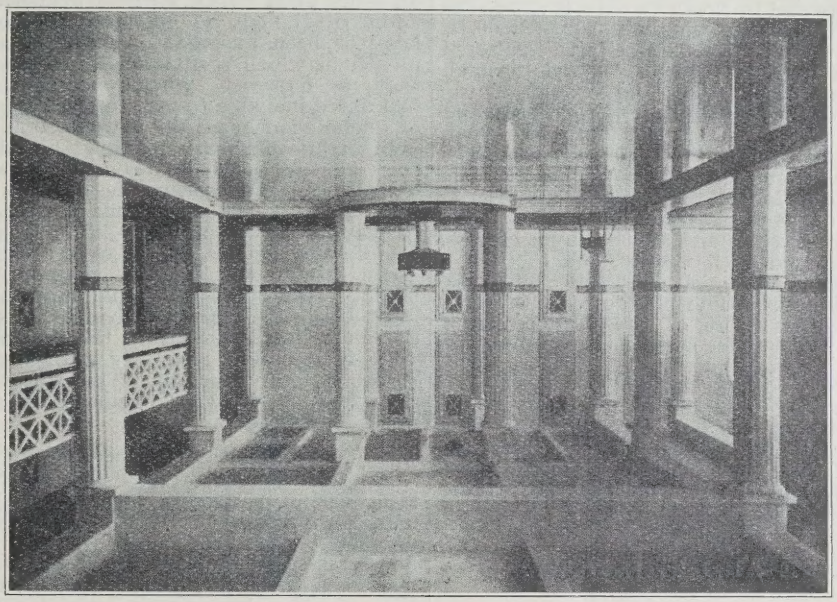
The thing that most strikes the tourist in Yugo-avia, whether medical man or no, is the extra-rdinary and intimate mixture of the new with the ld. In many districts where the natural conditions ake it poss-le agricul-re is in an dvanced tate, in hers it is the most ementary rt. In any places e resources advanced vilisation -hotels, ams, cine-as, good ghting, d sewer-e — leave thing to desired; others ere can as t be little t the most dimentary tempts in y direc-n.

In the ties of anjaluka d Sera-vo, the pital of snia, large streets, handsome shops, and fine proaches are intimately dove-tailed into rambling ental bazaars, and costumes reminiscent of every-ing from the pavements of Piccadilly to the Turkish eppes intermingle, though everywhere evidence is thcoming that progress is being made towards gher standards: in exteriors the young women d the way, for throughout Yugoslavia, when we t above the peasant class, the cream legs appear, e cropped heads, and trim clothes of the modern l.

Banjaluka is the site of a well-known Trappist nastery (Fig. 4) which the visitors were invited to spect as far as the outbuildings are concerned and e industries proceeding therein, but the monastic ablishment was not shown nor were many monks evidence. The Order is strictly one of silence, but e conducting monk took full and interesting vantage of the necessity of talking. He described e rise of the Trappists and their elaborate organisa-n to secure proper rules and adequate government; ridiculed the popular stories as to their conduct of and especially their method of burial; and he plained the considerable absence of monks from the ual fields of manual labour by pointing out that, versing the rules of St. Benedict, the Trappists were ly employed in manual labour for three and a half urs each day, but in prayer for seven hours. The standing features of the large buildings were the w church and the old monastery, which is now the st stately cowshed imaginable. The social advan-ges derived by Banjaluka from the monastery are o: first, within its walls a large orphanage is ported, and secondly the monastery has coördinated a valuable market for the local cheese, which is produced by dairies all over the surrounding area. The unspeakable road leading to the monastery communicates directly with a fine modern city thoroughfare which later dies away into a typical eastern market.

In Serajevo the blend of old with new, and east with west, was even more marked. The visitors were specially permitted to inspect one of the most famous mosques in Europe, while some of them took advantage of having a Turkish bath in a city which for generations suffered Turkish rule—an experience which proved that this form of balneology is very well conducted in London. Serajevo possesses fine streets, shops and bridges, and all the provisions for public health are in evidence, but the delightful market in its centre is an intricate network of alleys. (See Fig. 5.)

FIG. 7.



The Bath in the Toplice Hotel, Bled.

The same medley was noticeable at Mostar, the capital of Herzegovina, where the Roman foundations exist of the famous bridge which gave its name to the place. Here the bazaar quarter, running down numberless little streets alongside the river, and nestling under the arch of the bridge, conveyed the exact impression which many derive from pictures of Eastern commercial quarters; but a few yards from the jumble of booths and outhouses, comprising the bazaar, a broad modern bridge has been constructed, and a hotel erected that would have done credit to any capital in Europe. This was being run on modern lines for a crowd of guests, and as the old hostelry, adjoining one of the infrequent railway stations of the country, was also functioning briskly, an opportunity of drawing comparisons was offered; the new hotel may reproduce modern vulgarities in striving after better things, but the extent to which the old one had fallen behind what to-day the European traveller expects would be difficult to describe.

The Adriatic Coast.

From Mostar the party proceeded west, reaching the Adriatic coast at the delightful old town of Ragusa (Dubrovnick). Here all traces of oriental occupation had ceased, the old parts of the city being represented by the mediæval architecture of Venice as a ruling power in the world, while the more modern parts and the environment make up a holiday resort, where bathing in the sea and the sun can be enjoyed in lovely surroundings. Proceeding by boat from Ragusa through the many islands to Sparlato (Split) and by car to Sebenico (Sebenik), there was found at the latter city a perfectly modern hospital. This was built by the Austrians in 1883, but large additions have been made to it on a pavilion plan, and it now provides 500 beds, divided into medical and surgical wards, an

infectious block, and special clinics for dermatological and venereal cases, ophthalmic and neurological cases, and childbirth and maternity. Each of these divisions of the hospital is under a chief, while the institution is conducted by 11 medical men, with five lay administrators and a staff of 112 persons. The Mayor of Sebenico proved an enthusiastic cicerone both in the hospital and in his beautiful city—indeed, it is hard to say whether he was more enthusiastic over the modern cleanliness of the hospital or the ancient dignity of his church, of both which he has a right to be proud.

The last lap of the course was now reached and of the other places visited only two presented medical features, and each because of the opportunities offered for enjoyable holidays or convalescence. The first of these, Plitvice, situated in North Croatia, is the centre of a chain of 16 lakes at an altitude of over 2000 ft. (Fig. 2), framed in pine woods and inter-connected by waterfalls. A well-managed hotel stands on high ground facing one of the larger lakes, and all the country around offers beautiful air and scenery and pleasant walks. From Plitvice the journey to Bled, which is practically on the Austrian frontier, lies through the fertile and well-cultivated land of the Slovenes Bled is a delightful little settlement (Fig. 3) on the shores of a transparent blue lake; one hill is crowned by a castle and another by a church, the mountains abound with flowers, and there is a wide choice of hotels, of which the Toplice offers the agreeable provisions of a fine plunge bath (Fig. 7). Bled is the holiday resort of the fashionable of Yugoslavia, King Alexander setting the example.

Yugoslavia in the Making.

These brief notes, it is hoped, will show how vigorously modern civilised amenities are in the making in Yugoslavia; while for medical men the gratifying view is obtained that medicine is proving the great coördinating power in the reforms that are taking place on all sides.

MEDICINE AND THE LAW.

Criminal Lunacy Statistics.

IN the recently issued Criminal Statistics for the year 1926 the figures relating to criminal lunatics are interesting. The total of criminal lunatics received into asylums during that year was 147; this total can be resolved into two classes. In the one class are the "King's Pleasure lunatics," who have been found insane by a jury, either on arraignment or by the peculiar verdict of "guilty but insane." In the other class are the "Secretary of State's lunatics," who have been certified insane either before trial or after conviction. No fewer than 91 persons were certified insane after conviction while serving sentences in prison. So large a figure inevitably raises a doubt whether the law has not held many of them responsible for crime when, in fact, they were irresponsible through mental disease. It hardly seems satisfactory that out of 147 persons admitted as criminal lunatics during the year, hardly more than one-third should have been recognised as insane by a judge and jury. In the previous year, it may be mentioned, more than half the total admissions to criminal lunatic asylums were authorised by certificates given after the lunatic had been convicted and while he was serving his sentence in prison. Is there not a strong inference that these cases of insanity should have been detected earlier before the crime was committed? Can we afford to be dilatory in certification? Even in human life alone the criminal lunatic is costly to the country; out of 874 criminal lunatics in detention at the end of 1926 no fewer than 399 had been charged with murder. The danger and expense of the criminal lunatic to the country might be diminished if public opinion would support the medical profession when called upon to give a certificate under the Lunacy Act. So far, however, from receiving public support, the medical practitioner is constantly being reminded of his personal liability to heavy damages if he undertakes the unwelcome duties which lunacy legislation has imposed upon him.

Drunk or Not Drunk.

The Criminal Statistics show a steady fall in the number of non-indictable offences dealt with by courts of summary jurisdiction in respect of the intoxicating liquor laws. On the other hand, there is, of course, a steady rise in the number of offences against the Highway Acts in relation to the use of motor-cars. A generation ago the quinquennial average of offences by motorists was less than 2500; in 1926 the figure was 163,301. In a considerable proportion of these cases the accused is charged with being drunk while in charge of a motor-car, an issue upon which medical evidence is frequently adduced, though no adequate test of drunkenness has yet been evolved. A case was reported last month in which a divisional surgeon gave evidence that a motorist, when examined, was slightly inebriated but able to walk quite straight. He smelt of alcohol, continued the witness, but was extremely civil in his manner. "I say," he added, "that in the condition in which I saw him he was not able to drive a car safely because he did not know what he was doing . . . he was drunk in law; he was not fit to drive a car when I saw him; he was muddled." The stipendiary magistrate observed that he had no doubt in his own mind that the man was drunk but that, in view of the divisional surgeon's evidence, he must dismiss the charge of drunkenness. Presumably a man is not drunk from the magisterial point of view if he is only "slightly inebriated" and is able to walk quite straight. The witness's expression that the motorist was "drunk in law" was evidently unacceptable to the law.

Non-disclosure of Insurance to Juries.

A curious point of forensic etiquette was settled last week in connexion with the trial of claims for damages arising out of street accidents. It is an unwritten rule that counsel for the plaintiff should not mention to the jury the fact that the defendant was insured. The principle underlying this rule is that, if a jury knows that a rich insurance company stands behind the defendant, it will be more ready to decide that the defendant was negligent and to award substantial damages against him. There was no very strong authority in favour of this rule in the law reports until the recent case in which a plaintiff appealed against an order of his honour Judge Cluer discharging a jury in the Shoreditch County Court and directing that a case be tried before a fresh jury on the ground that counsel for the plaintiff had intimated to the jury that the defendant was insured. On the appeal being heard in the Divisional Court there seemed to be some doubt as to what counsel had actually said; but Mr. Justice Salter's judgment made it clear that the rule of non-disclosure is well founded and should be enforced by a judge at trial. On the other hand, Mr. Justice Talbot, while concurring in this judgment, suggested that the rule perhaps no longer worked for justice. No jury nowadays can help knowing that in the majority of cases of motor accidents the motorist is insured. Or, perhaps, added the judge, if the jury does not know that a defendant is insured, it may refrain from awarding heavy damages where such an award would be thoroughly justified. Mr. Justice Talbot suggested that it would be better to disclose frankly to the jury the fact of insurance or non-insurance, the judge being careful to give an express warning to the jury not to allow the fact of insurance to influence the verdict.

This view is fortified by some recent remarks of Lord Justice Scrutton on the changing temper of juries. Once, he observed, when motor-cars were rare, no jury would find in favour of a motorist; but now probably half the jurors own motor-cars themselves and can thus be relied upon to deal fairly with motoring cases. In fact, he added, it is difficult to get a criminal conviction of a motorist before a jury.

MULTIPLE DENTAL EXTRACTIONS.

To the Editor of THE LANCET.

SIR,—In his interesting address, which you ublished recently, Dr. Harvey Hilliard assumes hat major dental operations can always be safely arried out at one sitting. That is not my experience, or, I believe, that of dental surgeons in general. ach case should be treated on its merits with regard o the amount of sepsis present and the state of the odily resistance. When sepsis is severe and resistance ow it seems to me wrong to extract a large number of eeth at one time, for in my experience the amount of oxic absorption is directly proportional to the number f teeth removed and to the size of the resulting wound. he sockets are already infected and the teeth that e left do not play much part in absorption. In any ase it is inaccurate to speak of clearing out all septic atter from the mouth at one operation; the bone nd soft tissues are largely infected and extraction of eth does no more than remove the cause of the fection, leaving the bodily powers to deal with the eeper sepsis—a process which takes time. So-called ptic sockets—i.e., sockets from which the blood-ot has dissolved after extraction—are, I believe, arly always associated with undue laceration of the ssues and injury to the bone due to difficult or expert extractions.

Personally I have found the best procedure in cases here general toxic symptoms are present is to move the back teeth under nitrous oxide anæsthesia two operations with an interval of about a week tween, and then to allow a further fortnight for the ums to heal and the patient to deal with the absorp-on of toxins before the remaining front teeth are moved. In this way I find that the patient suffers tle if at all from general upset. I have a case in ind of a lady, 40 years of age, who had been three onths in bed with symptoms of mucous colitis sociated with severe anæmia suggesting sprue. Her ood count was R.B.C. 3·2 million, Hb. 60 per cent. d still falling; weight had dropped from her rmal 10 st. to 6 st. 6 lb. She had lost her 12 front eth and the condition of the remainder made it sirable to remove them all. Four were removed der gas with little general reaction, a few days later more when a severe exacerbation of colitis occurred d the patient became really very ill. Finally, er a fortnight, the remaining teeth were extracted thout mishap. She then made an uninterrupted covery, six months later her blood count being B.C. 5 millions, Hb. 100 per cent., and her weight st. Had the extractions all been carried out at e sitting my impression is that she would have died. I feel confident that the bad results to which Dr. lliard refers as arising when teeth are removed in ccessive stages are the result of not leaving sufficient ne between the stages. Three stages are in most cases fficient.—I am, Sir, yours faithfully,

A. H. JOHNSON, L.D.S. R.C.S.

London, April 27th, 1928.

TE TREATMENT OF ULCERATIVE COLITIS.

To the Editor of THE LANCET.

SIR,—On Dec. 4th, 1926, you published the address h which I opened a discussion on Colitis at the dical Section of the Royal Society of Medicine. it I described the excellent results which follow treatment of ulcerative colitis by the intravenous ection of antidysenteric serum. I was surprised refore to read in your leading article of April 28th t the results of serotherapy "were disappoint-; and its use has now been largely abandoned." e need for drawing attention to the treatment can gathered from the uniformly pessimistic views of the speakers in the discussion on ulcerative colitis at the Harveian Society, reported in your last issue. Sir William Willcox believed that many cases are hopeless from the first, and Dr. Bellingham Smith recorded a mortality of 24 among 46 cases. Mr. Lionel Norbury stated that several years of regular irrigation through an appendicostomy are required to effect a cure, and Dr. French advised colectomy as the only treatment he had known which ever gave good results.

In 1920, in the belief that the disease was really an aberrant form of bacillary dysentery, I tried the effect of intravenous injection of large doses of polyvalent antidysenteric serum. In the first case the result was little short of miraculous. A young man, who was almost moribund after being very ill for over a year, and in whom no improvement had followed an appendicostomy, recovered completely in a fortnight; five days after the first injection the sigmoidoscope showed that the innumerable ulcers seen a few days before had vanished, and nine days later the appearance of the mucous membrane was absolutely normal. In the eight years which have elapsed he has had one slight recurrence, which rapidly responded to serum treatment, and he is now perfectly fit. Since 1920 I have used antidysenteric serum as an essential part of the treatment in every severe case, generally with excellent results. I realise that the treatment may really be non-specific and nothing more than a form of protein shock, although in one case it proved very effective after a series of injections of ordinary horse serum had failed to produce improvement. The dosage I now use is 40, 60, 80, and 100 c.cm., injected intravenously on successive days, followed by 100 c.cm. for a few additional days. The reaction is occasionally somewhat alarming, but it is hardly ever dangerous.

The only fatal case I have had among my 25 hospital and private patients since I first tried the serum treatment was a woman, who died of broncho-pneumonia when she was improving as a result of an appendicostomy, performed on my advice a few weeks earlier. In three other cases an appendicostomy had been performed, but without obvious benefit; it was allowed to close when they came under my care, and the medical treatment was substituted with ultimate success.—I am, Sir, yours faithfully,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, April 30th, 1928.

To the Editor of THE LANCET.

SIR,—In the recent discussion on ulcerative colitis at the Harveian Society, as reported in your last issue, a note of pessimism in regard to treatment was struck which cannot be allowed to stand without comment. One speaker states that "while the symptoms might improve considerably, the sigmoido-scope usually showed that the condition was little altered. Ulcerative colitis was one of the most serious conditions of intestinal disorder and one of the most difficult to cure, *requiring several years of regular irrigation through an appendicostomy.*" Another speaker said that "*the condition was practically incurable and could only be relieved.* Of his 46 cases 24 had died" (italics mine). Serum treatment received no consideration, and the opener of the discussion said that it was not indicated in the ordinary chronic colitis of civilian practice. This so far conflicts with experience at Guy's Hospital that I feel it would be wrong not to join issue with the speakers quoted.

In 1921, Dr. A. F. Hurst first described [1] the successful employment of polyvalent antidysentery serum in chronic ulcerative colitis. Since then the method has been employed as a routine in his wards and was also employed in Dr. John Fawcett's wards. As assistant physician successively to Dr. Fawcett and Dr. Hurst, I have had opportunities of seeing their cases as well as my own. We all formed the opinion that the prospects of healing in ulcerative colitis were greatly improved, and that the period of

[1] Guy's Hospital Reports, 1921, lxx., 26.

hospitalisation was shortened and the mortality reduced by serum treatment. Cases, both early and late, and incidentally some with severe anæmia and wasting, have, after showing no response to other methods improved steadily after a full course of serum. Treatment has always been controlled by sigmoidoscopy, and I have personally witnessed complete healing of ulcers, together with clinical recovery, disappearance of blood from the stools, and reappearance of formed stools. I have had three cases under my care in Guy's in the last three months, two of these (cases of moderate severity) have been discharged convalescent after treatment lasting a few weeks only. The third, one of the worst cases I have seen, with an extremely hæmorrhagic type of lesion, is now, after six weeks, beginning to pass formed stools and shows commencing healing of her lesions. In 1925 a nurse with a three years' history of ulcerative colitis, complicated by thrombosis in both legs, was admitted to Guy's under my care in poor condition, with typical symptoms and sigmoidoscopic appearances. She had been given a small and quite inadequate dose of serum some months before her admission, and for this reason treatment had to be initiated with caution. After a full course she improved steadily. She weighed 9 st. 5 lb. on leaving the ward in November, 1925. In June, 1926, I saw her again and she was fit and well, weighed 11 st., and was passing two or three formed actions daily with a very occasional streak of blood. In March, 1928, I saw her again on account of a small ulcer on the leg, consequent upon the thrombosis. She remains perfectly well in herself and has no bowel symptoms.

I have had no occasion, in my own small series, to resort to surgical measures. I have, of course, seen cases in which the treatment was unavailing and when stricture or polyposis have developed the time for such treatment is clearly past. I can recollect only one case of my own in which improvement did not follow the treatment. In this case my house physician, through a misunderstanding, gave antistreptococcal instead of antidysenteric serum. It would seem either that the experience at Guy's is different from experience elsewhere, or that others have not given the method an adequate trial. A fuller discussion of the treatment, which must include large doses given by the intravenous route, will be found in the Proceedings of the Royal Society of Medicine, 1927 (No. 4), p. 367.

I am, Sir, yours faithfully,

Wimpole-street, W., April 30th, 1928. J. A. RYLE.

HAS THE CAMPAIGN AGAINST VENEREAL DISEASE BEEN A FAILURE?

To the Editor of THE LANCET.

SIR,—Mr. Johnston Abraham blesses the Edinburgh Corporation Bill, apparently because he seems to think that the compulsory measures which it desired to enforce would help the campaign against venereal disease which we all have so much at heart.

I have read his letter carefully, as his authority to speak on such a subject is unquestioned. He points out, I think with perfect justification, that treatment of syphilis under the voluntary system has been eminently successful. He thinks that the same statement cannot be made about gonorrhœa, and he points out a distinction between these two diseases—namely, that out-patient treatment is, on the whole, adequate for syphilis, but is inadequate for gonorrhœa. I think, in assuming that the conditions for treatment for gonorrhœa would be bettered if the Edinburgh Corporation had been able to secure the passage of the Bill, he is entirely mistaken. Perhaps he is not aware that before the second reading the Corporation dropped their clause asking for compulsory detention, and with that surely disappears Mr. Abraham's chief reason for support of the Bill. It is true, as I said in my speech upon the second reading, that the Corporation appear to think that they can, in fact, secure some form of detention under the Public Health Acts already on the Statute Book without fresh legislation for which they were at first pressing. This is a legal question upon which an eminent K.C. in the House of Commons has given me his opinion that these Acts do not, in fact, carry that sanction. Whether this be so or not I do not know, but I would point out that without hospital provision upon the large scale for detention, and for the long periods which the circumstances of the disease require, detention would be impossible to enforce. Surely it would be more sensible to provide the accommodation required for the proper in-patient treatment for gonorrhœa as advocated by Mr. Abraham, and to rely upon the voluntary system for persuading the patients to undergo the treatment. I do not think there would be any difficulty in achieving this purpose if the accommodation were there; it is the absence of accommodation, and not the lack of compulsion, that militates against the in-patient treatment of gonorrhœa upon the scale required by Mr. Abraham; and compulsion does not seem to me to be any necessary part of his proposition.

To ask for compulsion restricted to one town is surely a contradiction in terms. It could not, in fact, be compulsory under those circumstances. Compulsion must either be universal or must fail in its effect. An experiment could not be restricted to Edinburgh. Mr. Abraham says that medical opinion "all over Scotland" was in favour of the Bill. I should like to know upon what evidence he makes this statement. The Corporation, in presenting their case, could find no better medical support than the vote given at one meeting of the Edinburgh Division of the British Medical Association held a few weeks ago. The meeting was called by the promoters of the Bill; whipping was freely indulged in. I am informed that about 60 members attended the meeting, and inasmuch as there are some thousand persons (not 1500, as I am reported to have said) practising medicine in Edinburgh, that vote, which was not a unanimous but a majority vote, cannot be claimed as representing medical opinion, even in Edinburgh. I am not aware that any other steps have been taken to ascertain the opinions of the medical profession in Scotland, and should be glad to have the information.

I am, Sir, yours faithfully,

House of Commons, April 30th. E. GRAHAM LITTLE.

To the Editor of THE LANCET.

SIR,—It is more than a little interesting to know from Mr. Peart's letter in your last issue that in the silver preparations and in potassium permanganate we have remedies as effective in the treatment of gonorrhœa as is arsenobenzol in syphilis. Most venereologists have used, and still use, these preparations, but I know of no one who has found, by practical experience, that they are comparable in any way to arsenobenzol in syphilis. But then most of us use them by irrigation per urethram, which method, Mr. Peart informs us, is a faulty method of administration.

Mr. Peart says: "I have found injection of the vas absolutely reliable in dealing with every stage of the disease." It is very difficult to grasp this statement, which can only mean that Mr. Peart performs the operation of vasotomy on all cases of male gonorrhœa—acute, chronic, anterior, posterior—and its complications. The generally accepted view is that vasotomy is indicated in: (1) gonorrhœal arthritis, where it is found that the seminal vesicles are infected (as occurs in the majority of cases) and where it has been impossible to empty the vesicles by massage; (2) spermatocystitis of a chronic character; (3) azoöspermia, secondary to spermatocystitis. The operation, when done through an incision, is a comparatively simple one, if one follows the technique of Belfield [1] or of Kidd,[2] but it is not so simple that it is applicable to patients suffering from conditions

[1] Belfield, W. T.: Jour. Amer. Med. Assoc., April 22nd, 1905, and Dec. 25th, 1909.

[2] Kidd, F.: THE LANCET, 1923, ii., 213.

ther than those enumerated. My own practice after asotomy and the injection of (say) collargol, is to eep the patient in bed for four days.

If Mr. Peart actually, as his letter suggests, injects, rough the vas, preparations of silver and potassium rmanganate in *every* stage of the disease, it would e instructive to have a description of his routine d his technique for a case of acute gonococcal nterior urethritis. Every venereologist would be ad to compare the results of such treatment with rigation.—I am, Sir, yours faithfully,

E. TYTLER BURKE,
V.D. Medical Officer for the City of Salford.

April 28th, 1928.

To the Editor of THE LANCET.

SIR,—We do not wish to raise any word in opposition Mr. Johnston Abraham's plea for more beds for e treatment of gonorrhœa in women or to controvert s general statement on the deplorable lack of results hich have followed the introduction of the scheme t forward by the Ministry of Health in 1917. hen, however, he says that gonorrhœa in the female a most intractable disease and, as far as out-patient eatment is concerned, cure is exceedingly difficult, e desire to point out that, though this may be true the methods commonly in vogue, it is most certainly t true of the method of treatment by diathermy troduced by us at St. Bartholomew's Hospital and actised there since 1919.

A preliminary communication on the subject was ade to the Section of Electro-Therapeutics of the oyal Society of Medicine in January, 1922, in which e were able to state that 12 cases which had come th a diagnosis of gonorrhœa, bacteriologically nfirmed, had been treated, and that in all but one these, after three to five applications of diathermy, ere was no clinical or bacteriological evidence of fection, whilst subsequent observation over periods nging from two months to one year showed that the fection had been definitely removed. At the British edical Association meeting held at Portsmouth in e following year it was reported that six additional ses had been treated, and that of the total number of all but one had finally been found free from fection.

Since these communications we have continued to eat gonorrhœa in women by diathermy with satisctory results. The success is as invariable as the st series of cases led to us suppose, but probably ring to a different class of case coming under eatment, it has been realised that the number of plications required is sometimes more than the ree to five given in the first series, some requiring many as 12. The treatments are given twice weekly. about ten days, therefore, many cases are rendered e from infection, whilst some take as long as six eks. The potency of diathermy is further shown the invariable disappearance of metastatic infection d the absence of communication of infection on arriage or on resumption of marital relationship. ull descriptions of the method of application have en given in a book [1] published by us on the subject d in papers read at the Royal Society of Medicine [2] d articles in various journals. The cases, with few ceptions, have been treated as out-patients, and ere can be no doubt that the method is suitable for e under such conditions. It must be strongly phasised, however, that the treatment of the pelvic gans by diathermy cannot be properly conducted by rses, orderlies, or other attendants who are not roughly acquainted with pelvic anatomy and the cessary manipulations and passage of electrodes. oper skill and knowledge must be exercised to ensure ccess and to prevent injury to the patient. In our nds an accident or untoward event has never curred.

This letter has not been written for the purpose of ging that treatment of gonococcal infection by athermy should be adopted at the special treatment centres. The method may be too costly, or unsuitable for some other reason. This is not specially our concern. Our object is to point out that there is a means of bringing gonococcal infection in women to an end in a short space of time, and almost invariably, and that the method is suitable for out-patient treatment. The results we have obtained have been confirmed by workers scattered throughout this country and in other parts of the world.

We are, Sir, yours faithfully,

E. P. CUMBERBATCH.
C. A. ROBINSON.

SPLENOMEGALY ASSOCIATED WITH ASPERGILLOSIS.

To the Editor of THE LANCET.

SIR,—The annotation under this heading in THE LANCET for April 14th (p. 767) will perhaps serve to direct attention to the fact that in France, for a year or two past, it has come to be generally believed that some cases hitherto regarded as cases of Banti's disease are associated with the presence in the spleen of mycelial structures now commonly known as *Aspergillus nidulans*. Those who believe that this mycelium is causal to the symptoms speak of the conditions as constituting *la mycose splénique de Nanta*, or Nanta's mycosis of the spleen, in honour of Nanta and the Algerian school of medicine. Others, like Oberling, question the causal importance of the organism, in at any rate the sense of Nanta, whilst a third group frankly "does not believe" in it as causal at all. That such a mycelium does occur in certain cases appears, however, to be the fact.

We need not therefore forget that the presence of a mycelium in the spleens of certain cases of splenomegaly and Banti's disease was demonstrated by Dr. A. G. Gibson, of Oxford, in a paper read before the Royal Society of Medicine.[1] Oddly enough, Léon-Kindberg, in his article [2] published in 1927 makes mention of Dr. Gibson's later work,[3] declaring him "nettement partisan de l'origine infectieuse" of Banti's disease, then going on to make mention of the first reports by Nanta, Pinoy, and Gruny, ascribing causality to a streptobacillus. This work of these observers seems to have been abandoned by them in favour of that later which, alleging the presence of the *Aspergillus nidulans* or *nantæ*, does not seem to do more than repeat what Gibson had already shown. And a rather bitter attack by Langeron,[4] upon the work of Nanta, seems to have been made in ignorance of the importance of the work already done in England.

One thing is clear: the appearances first demonstrated at the Royal Society of Medicine in 1913 are mycelial and constant for a group of cases, whatever may be the importance finally allotted to them.

I am, Sir, yours faithfully,

F. G. CROOKSHANK.

Wimpole-street, W., April 23rd, 1928.

LIVER IN PERNICIOUS ANÆMIA.

To the Editor of THE LANCET.

SIR,—In your leading article last week you do not mention a point of view which, as it seems to me, goes far to explain the beneficial results accruing from the treatment of pernicious anæmia with liver or an extract thereof. It is held by many (with whom I am personally in agreement) that the true pathology of the disease lies in the persistence of embryonic erythropoiesis in the liver, which normally ceases at birth. In consequence, the normal method of production of erythrocytes in the bone-marrow, via the normoblast, never properly develops. When therefore some extraneous factor comes into play—

[1] R.S.M. Proceedings (Medical Section), 1913, vii. 7–9.
[2] Nouveau Traité de Médecine, ix., 677.
[3] THE LANCET, 1921, ii., 885.
[4] Presse Médicale, April 18th, 1928, p. 482.

of which sepsis, hæmorrhage, and syphilis are the most common—the bone-marrow receives what may be loosely described as a fatal blow. The evidence for this is chiefly to be found in the presence of embryonic erythroblasts in the circulating blood, and the process itself can be seen in situ in the liver post mortem. Quite recently I have examined a portion of liver removed during the operation of splenectomy in a case of pernicious anæmia. The notes will shortly be published in full, but I may say here that there could be no doubt that the case was one of true pernicious anæmia, or that the appearances in the liver were those of embryonic erythropoiesis. Incidentally, the organ contained no free iron. The blood picture has returned to normal under treatment by raw liver.

I submit that the explanation of the action of liver diet may be found in the view that a liver in which embryonic erythropoiesis is persisting is deficient in the production of the normal hepatic stimulant to, or control of, the bone-marrow; administration of raw liver, or an active extract thereof, supplies this substance and thus in time the bone-marrow is able to resume its normal functions. In the "embryonic" conception of pernicious anæmia, hæmolysis and achlorhydria are regarded as accessory and not causative factors, and not as essential for the diagnosis of the disease. Your leading article would seem to support this last point.

I am, Sir, yours faithfully,

A. KNYVETT GORDON.

Bedford-square, W.C., April 28th, 1928.

INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—The procedure I prefer for the treatment of varicose veins is the one I saw Prof. Sicard using at his Paris clinic. The needle is inserted while the patient is standing on an operating table; when blood has been drawn he is directed to lie down very slowly; the injection is made in this position. If the vein is large the patient is recumbent from beginning to end.

The reasons for this preference are as follows. Normally the flow of blood is from the superficial to the deep veins. Sicard was able to demonstrate by injecting lipiodol into varicose veins that in the horizontal position the blood from the superficial veins had no tendency to join the deep veins; with the patient in this position, therefore, the sclerosing solution is not carried away by the blood stream, and is thus able to act locally. The other reason is that with the patient recumbent we are dealing with a comparatively empty vein, so that the sclerosing solution has every opportunity to come in direct contact with the endothelium, a most important and essential factor for success.

When the patient is erect the flow of blood in the varicose vein is centrifugal and not towards the heart. This has been shown by Tentzer, Sicard, and Gally, and Delater, working with solutions opaque to X rays, and by Magnus, who used a hæmodromograph. The radical operation, which has until recently been the treatment par excellence, is unsatisfactory because one can never be certain that the valves of the communicating veins between the superficial and deep vessels are not so inefficient as to allow a reflux from the deep veins into the superficial ones; and here, no doubt, lies the cause of the innumerable failures of surgical intervention. The aim of the treatment with a sclerosing solution is to obliterate the entire varicose system right down to the valves leading into the deep veins, and it is the only treatment which can claim to accomplish it. The principle is an old one, being based on the observation that injury to a vein may lead to thrombosis and spontaneous cure. The injected sclerosing fluid injures the intima and penetrates the tunica muscularis to reach the adventitia, as has been demonstrated by Tentzer. This observer added collargol to a solution of sodium salicylate, which he injected into a varicose vein, and on removing the vein a few hours later was able to show the presenc of collargol (and therefore of sodium salicylate throughout the thickness of the venous wall and eve outside it. The opposing venous walls swell and com into contact with each other; at the same time network of fibrous tracts is formed, which ancho themselves to the whole surface of the injured endo thelium and to the whole thickness of the wall. Al the fibrous deposits adhere to these tracts, and a fre clot is not formed. By way of these tracts th thrombus is firmly attached to all three layers of th venous wall and is unable to detach itself, so tha embolism is impossible.

My experience of many hundred cases is entirel based on the use of Génévrier's quinine solution (star with 0·5 c.cm. and do not go beyond 1·0 c.cm.) an of 30 to 40 per cent. sod. salicylate, of which 1 t 3 c.cm. may be used. Looking through the British an continental papers on the subject I have counted th number of administrations; they almost reach si figures, but not a single case of embolism due to th use of the above-named substances is reported. Ther have been a few fatal cases, but they were due t NaCl + Glucose or other sclerosing substances.

I fully endorse the contra-indications mentioned b Mr. Maingot and Mr. Carlton, but would add tha pregnancy is, in my opinion, an absolute contra indication to the use of any sclerosing solutions, a the varicose state is here chiefly due to change endocrine metabolism and might entirely disappea after parturition. Certain forms of varicose vein such as those resembling a sponge and those com plicated by cutaneous lesions, do not respond we to the treatment. Before deciding whether the case i suitable it is, of course, essential to be sure that th patient's discomfort is actually due to his varicos veins. The coincidence of varicose veins wit neuritis, periostitis, arthritis, and of flat-foot is ver liable to cause confusion.

I am, Sir, yours faithfully,

London, W., April 23rd, 1928. A. A. MILLER.

To the Editor of THE LANCET.

SIR,—In a paper published last year [1] I recommende that injections should be made with the patient in sitting posture, the chair being placed on a dais fo the sake of the operator's convenience. Since then however, I have treated over 100 cases in the followin manner, and find it much more satisfactory.

I still employ my dais, but the treatment can be accon plished quite well without it. The patient remains standin and puts his weight on the leg to be treated. A pneumati tourniquet is then placed above the knee and the pressure i it is raised sufficiently to restrict the venous flow. (On m own tourniquet I have an aneroid manometer which I caus to register 130 mm. of Hg, but this, though a useful refine ment, is, of course, not a necessity.) The patient is the asked to lie down; I use a reclining chair with an adjustab foot-rest, but a consulting room couch does almost as wel The needle without the syringe is inserted into the vein an as soon as a bead of blood shows in its lumen the tourniqu valve is unscrewed, the leg is elevated above the plane of th body, and the veins are emptied by gently but firml stroking towards the thigh, and the injection proceeded wit secundum artem.

I am aware that many authorities do not agree wit the use of the tourniquet, but if the following precau tions are taken I am sure this method will be foun to be most efficient.

(1) Be sure that the vein shows up as a definite varico vein before the tourniquet is applied, and is not merely normal vein which has dilated owing to the extra pressu imposed by the tourniquet. (2) Do not forget to remove th tourniquet pressure the moment the vein has been entere

The following appear to me to be the advantages this method. (1) It is much easier to enter th selected vein with the patient's leg in the horizont plane. (2) Since the operator can sit comfortab alongside the patient and rest his hands on the lim he has a much steadier control upon the syringe an needle, and this, I think, is a great advantage whe

[1] Practitioner, 1927.

is so important that the point of the needle shall emain within the vein throughout the injection. 3) The vein being collapsed and practically free from lood, the solution will act in greater concentration nd will be more constant in its action. (4) Since the atient is either prone or supine there is less tendency o faintness and certainly less danger should this occur.

For sterilising the skin over the vein a 5 per cent. olution of thymol in alcohol will be found efficient. n withdrawing the needle from the vein I firmly ress one finger over the puncture and keep it there or a minute or so, when I apply a small lenticular bject to replace my finger and keep steady with a elastic band. This remains in position for ten inutes, after which I allow my patient to stand up nd conclude the "sitting." I prefer the salicylate olution for the larger veins, but feel that the quinine-ethane is more suitable for the small veins or for eins with very degenerated walls. Finally, I would commend that possible idiosyncrasies should be ept in mind. Quite recently a patient told me, on eing questioned, that she was once given five grains of pirin and collapsed after it, and that a tiny dose of uinine always produced a most distressing rash.

I am, Sir, yours faithfully,

RONALD THORNHILL.

Harley-street, W., April 23rd, 1928.

DOCTORS AND THE NURSING HOMES REGISTRATION ACT, 1927.

To the Editor of THE LANCET.

SIR,—This Act is of interest to the many hundreds, not thousands, of doctors who receive into their ivate houses persons known as "private patients" paying guests—this latter euphemism being opted to solace the patients or relatives. The sition is this. Before July 1st next every such ctor who receives into his private house even only e mentally or physically ill patient, and includes an agreement or contract the provision of nursing," whether by a nurse or attendant or herwise, will have to register that house, which ll become then subject to inspection, from basement roof and in all its contents, domestic and pro-sional, whether alive or dead, by the local super-ing authority, displaying in addition, in a con-cuous position in his house, his certificate of istration.

There are only two ways for him to escape from s objectionable position. Either he should cease, from July 1st, to receive such patients, or if nursing" is required, *he should stop the provision nursing*, arranging that this should be an extra ond his contract. He should recommend to the atives a suitable person *for them* to engage, charge m for board and residence, receive as the agent m the relatives the wages, and, handing them r from time to time to the nurse or attendant, ain a receipt for same addressed to the relatives. the case of those doctors whose houses cannot be ducted on these suggested lines and must, in sequence, become registered, I would urge that y get into touch as soon as possible with their l authority (county or county borough) and obtain opy of the draft by-laws in order to see whether y contain anything thought objectionable. If then the recognised local medical organisation uld be urged to take immediate steps before it ound to be too late.

I am, Sir, yours faithfully,

ove, May 1st, 1928. E. ROWLAND FOTHERGILL.

EXPERIMENTAL PHONETICS.—At the Linguistic gress held at The Hague in April, an International ety of Experimental Phonetics was founded, the object hich is the promotion of scientific research in experi-tal phonetics. The society will issue a bulletin from to time. The membership fee for 1928 is 5*s.*, and lications, with fee, may be sent to Prof. E. W. Scripture, delhofgasse 4, Vienna, Austria.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

REGISTRATION (BIRTHS, DEATHS, AND MARRIAGES) BILL.

On Friday, April 20th, Captain GUNSTON, in moving the second reading of the Registration (Births, Deaths, and Marriages) Bill, said it was intended to deal with the chaotic system of remunerating and appointing registrars. Although it was a national and centralised service, the officers engaged in it were partly paid by the Guardians, partly by the Exchequer, and partly by fees from the public. The Bill did not propose to take away the good fortune of any officer who was earning good remuneration from fees, but it proposed that when a vacancy occurred, the Registrar-General should be entitled to declare the office a salaried one, and that if there was an excess of fees in the office after the salary had been paid, the balance should go to a central fund to make up the salaries of underpaid officers. Any officer holding a non-salaried office could apply to the Registrar-General to have his office declared a salaried one. Clause 2 provided that the holders of salaried offices should be paid on a scale of salary approved by the Treasury. The clause also abolished the watertight principle of sub-districts, and allowed officers to function over wider areas. Clause 4 made it lawful for the Minister to increase the statutory fees up to 50 per cent. Clause 5 would enable the Registrar-General to give the public the new services which had been demanded since the passing of the original Act. The Bill also provided that proper travelling expenses should be paid.

Mr. G. PETO seconded the motion.

Mr. SCURR moved the rejection of the Bill. He said he opposed the Bill, not because he was opposed to the principle of these officers becoming salaried officers—payment by fees was an absurdity—but because he thought the methods proposed in the Bill would not attain the objects desired. Further, such a Bill should have been introduced as a Government measure.

Mr. MARCH, who seconded the motion for the rejection, said the Government should have been bold enough to bring forward a Poor Law Reform Bill of their own dealing with the whole question.

Payment by Fees Discredited.

Sir KINGSLEY WOOD said that the Minister of Health was very keenly interested in the subject of this Bill. He looked with considerable anxiety on the position of a good many of the registration officers up and down the country. The remuneration of these officers bore no relation to the amount of work that they did, or to the responsibility which was involved. The average total receipts per registrar at present were approximately £137. On the other hand, a number of registrars in larger districts enjoyed very large fees indeed, and in some cases those fees were in excess of what would be regarded as whole-time salaries for such work. Payment by fees had long ago become discredited in this country, and this was the only branch of the public service in which this obsolete system survived. It was far better that the appointment of registrars should rest with the Registrar-General rather than with the boards of guardians. The Bill would not involve any further cost to the State, although it might involve increased fees in some cases. That was only right, as the rate of fees was fixed many years ago, and had no regard to the present conditions. When the Bill got into Committee the Government and other Members of the House might desire to offer suggestions regarding its exact machinery and details, but so far as the principle was concerned there need be no alarm from the point of view of the public.

Vital Statistics.

Colonel FREMANTLE said he was particularly concerned with the social services, and those services, especially in relation to public health, depended very largely upon the wonderful volume of facts got together by the registration system of the country. The whole system of vital statistics was dependent, mainly and fundamentally, on this system of registration, and the vital statistics were essential for purely financial matters, as well as for other purposes for the profession of the actuary with all that it implied. They could constantly check their system of administration according to the results of vital statistics. It was used for research, and could be used much more for research if it was properly centralised as a service. A good many members, especially those interested in scientific matters, were very much concerned with the question of eugenics and the future development of the race. The Eugenic Society had written to him as follows:—

"The advantages to be obtained from accurate statistical information concerning many social questions are becoming more widely recognised . . . . The separate register now

maintained for different purposes should be amalgamated . . . . This Bill would facilitate the introduction of those minor reforms which must from time to time be found to be desirable. It may be hoped that the ascertainment of the differences in the rate of multiplication of the different social classes would thus be made possible, this being a subject of great practical importance so far as the future welfare of the nation is concerned."

There was no end to the possible development of this system. A system had been developed very largely in recent years under successive Registrars-General, and their efficient staffs at Somerset House, but they needed a proper method of control such as was given in this Bill; and he cordially supported the measure.

Whole-time Service.

Dr. VERNON DAVIES said he thought it would be impossible to make this a whole-time service. It was not difficult work; it was not work that required a very high standard of education. In spite of what had been said by Colonel Fremantle, the work of a registrar of births and deaths was to-day almost entirely the notification of certain facts, and these records in course of time went up to London, to the Registrar-General, in whose department all the important work was done. It was absolutely impossible that the work in connexion with the vital statistics could be done elsewhere than in a central place. He did not see how they could make this a salaried service in the smaller districts. There was no reason, however, why means should not be adopted to try to improve the position of the men at present in the service. The position of the registrars had varied considerably in recent years. The building of hospitals and maternity homes in certain districts had had a considerable effect. He had had a return sent to him confidentially by the registrar of a district close to which two hospitals had been built. He informed him (Dr. Davies) that whereas in 1921 he registered 782 births and 340 deaths, by 1927 the number of births had been reduced to 326, and the number of deaths to 262. On the other hand, in the case of one of these hospitals the number of births was 630, and in the case of the other the number of births was 200 where previously there had been no births. In this particular case the registrar of births and deaths in the district in which the hospitals were situated had done exceedingly well by having a great increase in remuneration from fees, but the registrar who had been in practice for many years on the surrounding borders had seen his income very materially decrease, and he (Dr. Davies) would like to know upon what basis of fees that registrar was to be dealt with in the future. He gave general support to the Bill, but expressed the hope that he might be on the Committee which dealt with the measure, so that he might be able to raise one or two points of detail.

The Bill was read a second time.

PROTECTION OF DOGS BILL.

Sir ROBERT GOWER moved the second reading of the Protection of Dogs Bill.

Lieut.-Commander KENWORTHY seconded the motion. He said there were two classes of people who were in favour of this Bill, first of all dog lovers, and secondly those who, on grounds of humanity and decency of feeling, objected to the dog being used as a subject for vivisection and for experiments. There were other animals that could be used.

Dr. LITTLE said he wished to bring forward very special reasons why the dog should not be exempted from these experiments. The dog was absolutely necessary for this type of work, because it was most like the human being in regard to its organs and many other parts of its body. Dr. Little was still speaking at 4 o'clock, when the debate was automatically adjourned under the rules of the House. The Bill was accordingly "talked out."

NATIONAL HEALTH INSURANCE BILL.

THE National Health Insurance Bill was considered by Standing Committee C of the House of Commons on April 24th. Mr. WILLIAM NICHOLSON was in the chair. The Bill amends the National Health Insurance Act 1924, and other enactments relating to health insurance by providing for the application towards the cost of benefits and expenses of administration of certain moneys consisting of contributions, as to which there is either no provision in the existing Act for their being so applied, or they could only be applied in this way in a manner that would not involve a pari passu payment by the Exchequer. The Bill also proposes to bring two additional classes of workers under compulsory insurance. In both respects a fresh liability is imposed upon the Exchequer.

Clause 1: Amendments Moved.

Clause 1 makes provision in the case of a man who becomes unemployed before June 30th or Dec. 31st, that should he become ill prior to the prescribed date, such illness is not to be taken into account as part of the two years' period during which he would be kept in benefit under the Act.

Mr. WHITELEY moved an amendment seeking to extend that position so that if an insured person became incapable of work after ceasing to be employed, the period during which he was incapable should not be taken into account.

Mr. CHAMBERLAIN (Minister of Health) said he hoped the hon. Member would not press the amendment. While they wished to be generous in these matters, some regard must be had to the financial position of the various societies, and the Committee must remember that very generous provision for insured persons was already made under the Clause. The proposal of the hon. Member might mean a very considerable extension of free insurance, and he thought that it would be altogether unreasonable to ask the societies to carry such a burden.

The amendment was withdrawn.

Mr. NAYLOR moved an amendment to enable an unemployed man to be treated as an insured person for a further period of five years beyond the maximum period of two and three-quarter years provided in the Bill.

Mr. CHAMBERLAIN said that an insured person, even after the two and three-quarter years, might be given a still further period of free insurance if he happened to be ill at the beginning or end of the original period. To ask that a man, after having had two and three-quarter years of free insurance, should be given another five years was to ask for something which could not possibly stand examination.

Mr. MELLER said that the Committee ought to bear in mind that they were dealing here not with some charitable gift from the State, but with an insurance scheme. All the concessions given under the Bill would cost money, and he understood that the Actuary had been searching round in every nook and cranny to find money in order to give these concessions, and before those concessions were extended it ought to be shown whence the necessary money could be obtained.

Mr. RHYS DAVIES said that the position was this: provision was already made under the Bill whereby a man who was insured under the National Health Insurance Act, on reaching the age of 60, could be unemployed for five years and yet be entitled to the old-age pension at 65, and his widow would be entitled to pension and allowances if there were any children of pensionable age. All those who supported the amendment wanted was, that the same principle should apply also to the younger men. The number of cases covered by the amendment could not be very large, and it would be a very kindly act on the part of Parliament and of the Minister of Health to do something for these people.

Dr. DRUMMOND SHIELS said he would like to emphasise the effect on the physical condition of men which was caused by a number of years of unemployment. It was very important to keep in mind the linking-up of this scheme with the Contributory Pensions Act. Many of these unemployed men had not been sufficiently fed and they were very liable to illness and death. They had been told that this was an insurance scheme and that they ought to remember that point when considering its finances, but they should also remember that an insurance scheme gave certain benefits and was supposed to ensure that those benefits would be provided.

Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health): You cannot say that; the benefits are definite under the Act and are subject to conditions.

Dr. SHIELS said that they must remember the obligatory side as well as the financial side. He hoped, if the proposal made in this amendment could not be accepted in its entirety, that the Minister would at least keep these men within the scheme, so that a loss of benefit to widows and children would not result.

Mr. CHAMBERLAIN said that if they carried the argument that a person who became permanently unemployable was nevertheless morally entitled to receive the benefits which he would have received had he been employed to its logical conclusion, they could not stop at five years; they must say that whatever period was necessary to enable the man to fulfil the conditions, would be made up for him. He submitted that that was not a reasonable proposition. The provision already made under the clause had not been fully appreciated by the Labour Party. The people who were left out of consideration were only those who for one cause or another were permanently unemployable and therefore not suitable subjects for insurance.

The amendment was rejected by 18 votes to 15.

Clause 2: Inmates of Hospitals.

On Clause 2 (Amendment of Section 17 of the principal Act as to inmates of hospitals, &c.),

Mr. BROAD moved an amendment to omit the provision that benefit in the case of an insured person who was an inmate of a hospital, sanatorium, or similar institution, should be paid in weekly instalments of not less than 10s.,

ıd not more than £2 per week, and to substitute the ovision that such benefit might be paid in a lump sum.
Mr. CHAMBERLAIN said that in this provision of the ill they were dealing with the recommendations of the oyal Commission. The Consultative Council endorsed ıe recommendation of the Royal Commission, and it was ith their assent and approval that the Bill had been afted in its existing form. He could not therefore agree the amendment.
After further discussion, during which several Labour embers urged the Minister of Health to reconsider his titude on this matter,
Mr. CHAMBERLAIN said that without committing himself that stage to anything, he would be willing to consider is question a little further.
The Committee adjourned.

SUNDAY TRADING BILL.

In the House of Commons on Tuesday, May 1st, Sir F. ANDERSON asked leave to introduce a Bill to restrict the pening of shops on Sunday. He said that no Bill had been assed through the House on this subject since the reign f Charles II., when a measure was passed making Sunday ading illegal and imposing a fine of 5s. for each offence. hat Act still remained the law of the country, save for an ct promoted by the London County Council which pro- ibited street trading by hawkers except under licence sued by the borough council. It was generally realised ıat the present law was obsolete and not fit to deal with esent-day conditions. The present Bill represented the eatest common measure of agreement and reconciled nflicting interests of all kinds. It did not deal with such aces as public-houses, other places of refreshment, or the le of newspapers and periodicals, and medicines and rgical appliances. It also provided for the sale of many her necessary commodities during specified hours.
Leave was given to introduce the Bill, which was brought and read a first time.

HOUSE OF LORDS.

TUESDAY, MAY 1ST.

Local Authorities (Emergency Provisions) Bill.

The Local Authorities (Emergency Provisions) Bill, a easure which appoints the Metropolitan Asylums Board the body to control the distribution of the Metropolitan mmon Poor Fund, was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 25TH.

Medical Services in Palestine.

Colonel WEDGWOOD asked the Secretary of State for the olonies whether the Government medical service in lestine was open to women doctors as in the Federated lay States and East Africa as well as in Great Britain; d, if not, for what reason.—Mr. AMERY replied: There as yet no Government medical appointments in Palestine n to women doctors. The special services for which men doctors are employed in the Federated Malay States d Tropical Africa are adequately provided for in Palestine other agencies.
Replying to a further question by Mr. KELLY, Mr. AMERY d that the special positions dealing with infant welfare ich ordinarily were filled by women doctors were met in lestine with a widespread service of nursing and midwives d, in the opinion of the Government, there was no special ening for women doctors in other capacities.

Maternal Mortality Research.

Sir ROBERT THOMAS asked the Minister of Health whether, iview of the continued high rate of maternal mortality, would consider granting financial aid to research into ts question.—Sir KINGSLEY WOOD (Parliamentary retary to the Ministry of Health) replied: My right hon. nd is proposing to appoint a special committee on ternal mortality, one of whose functions will be to consider need for further research into the question, and that mmittee will no doubt report whether any further financial sistance could usefully be provided for this purpose.

Use of Sulphur in Barley Milling.

Ir. WESTWOOD asked the Minister of Health if he was are that the Public Health (Preservatives in Food) gulations, in so far as the prohibition of the use of sulphur he milling of barley was concerned, was having a serious ct upon the home-barley milling trade; that permission been granted to the cornflour millers to use sulphur; that the granting of permission to use a smaller per- tage of sulphur in the milling of barley than was now d in the milling of cornflour would avoid further unemploy- ment in the barley milling trade; and was he prepared favourably to consider granting to barley millers a similar concession to that granted to cornflour millers under the foregoing regulations.—Sir KINGSLEY WOOD replied: My right hon. friend has received representations that the prohibition of the treatment of barley with sulphur dioxide is prejudicial to British barley millers, and he has also received representations that the prohibition is in the interests of British barley growers. The prohibition applies equally to home-milled and imported barley, and my right hon. friend does not see why any efficient miller should be adversely affected. There is no true analogy between barley and cornflour, since in the former case sulphur dioxide is merely used as a bleacher, and in the latter it is an essential part of the process of extracting the starch from the grain. My right hon. friend does not consider that the addition of this undesirable substance to food can be justified on the ground that it has a bleaching effect, and he regrets, therefore, that he cannot reconsider the decision not to allow its use in barley.

THURSDAY, APRIL 26TH.

Tuberculosis in England and Wales.

Captain BOURNE asked the Minister of Health the estimated number of persons in England and Wales suffering from tuberculosis on Jan. 1st, 1928, or on the latest convenient date.—Mr. CHAMBERLAIN replied: According to the returns furnished to my department, the total number of notified cases of tuberculosis which remained on the registers of local authorities on Dec. 31st last was 363,187.
Captain BOURNE asked the Minister of Health the total number of sanatoria for the treatment of tuberculosis in England and Wales, distinguishing between those maintained wholly or partially from public funds and those supported by fees paid by the patients.—Mr. CHAMBERLAIN replied: The number of institutions approved by my department for the residential treatment of tuberculosis under the schemes of local authorities in England and Wales (excluding general hospitals) is 349, of which 215 have been provided by local authorities and 134 by voluntary bodies. These are all maintained wholly or partially out of public funds. I have no complete information regarding those institutions not so maintained.
Captain BOURNE asked the Minister of Health the number of persons in England and Wales who underwent treatment for tuberculosis in sanatoria during the year 1927, and the average duration of such treatment.—Mr. CHAMBERLAIN replied: Complete particulars for the year 1927 are not yet available. During 1926 the number of persons who received residential treatment for tuberculosis under the schemes of local authorities was 63,680, and the average duration of treatment was approximately 150 days.

Small-pox among Casuals.

Mr. KELLY asked the Minister of Health whether, arising out of the necessity to continue the arrangements for the detection of small-pox among casuals and the issue of Circular 830, pointing out that casual wards should not be closed except in the most exceptional circumstances, he could give any indication as to the extent the advice contained in the circular was being carried out by boards of guardians who had closed, or were contemplating the closing of, casual wards.—Mr. CHAMBERLAIN replied: The circular in question deals with the detection of small-pox among casuals and advises boards of guardians that, in the event of a case of small-pox being found in a casual ward, the temporary closing of the ward should not be necessary if certain precautions are taken; the circular does not in any way deal with the question of the permanent closing of redundant casual wards.

Deaths of Women in Pregnancy.

Sir BASIL PETO asked the Minister of Health whether his department had any statistics of the number of deaths of women in pregnancy from septic peritonitis; and whether he proposed to take any steps to safeguard them against the onset of this condition at maternity welfare centres.—Mr. CHAMBERLAIN replied: The last year for which a detailed classification of the deaths due to pregnancy and child-bearing is at present available is 1925, and in that year there were 84 deaths from septic peritonitis, perimetritis, and pelvic peritonitis. As regards the second part of the question, it is one of the duties of the doctors at ante-natal clinics to detect and remedy any focus of infection which might later be a cause of septic infection.

MONDAY, APRIL 30TH.

Sleeping Sickness in Mozambique.

Sir ROBERT THOMAS asked the Secretary of State for the Colonies whether he was aware that a commission, appointed by the Lisbon Government, was investigating the causes of sleeping sickness in Mozambique, with special reference to the tsetse fly; and whether our own medical service in

East Africa was collaborating with the Portuguese societies in this matter.—Mr. AMERY replied: My attention has not been drawn to the appointment of this commission, but I will ask my right hon. friend the Secretary of State for Foreign Affairs to make inquiry in the matter. A number of such missions, including several in our own territories, are engaged in the investigation of sleeping sickness problems in Africa, and endeavours are made, through the medium of a subcommittee of the committee of civil research, which deals with this question in its larger aspects, to ensure that effective collaboration is maintained among workers engaged in the study of sleeping sickness.

Local Government Reform.

Mr. HURD asked the Minister of Health if, and when, he would circulate his local government proposals for discussion by the local authorities concerned.—Sir KINGSLEY WOOD replied: Yes, sir. My right hon. friend hopes to circulate a memorandum for discussion by local authorities at an early date.

Mr. HURD asked the Minister of Health if he would give an assurance that the proposed Local Government Bill would await the Report of the Royal Commission on Local Government, now completing its investigations.—Sir KINGSLEY WOOD replied: No, sir. The programme of the Government must proceed on the lines announced by my right hon. friend the Chancellor of the Exchequer. There is, however, a very substantial field of inquiry within the terms of reference of the Royal Commission which is not covered by the Budget proposals, and as at present advised, my right hon. friend the Minister of Health sees no reason to interrupt the satisfactory progress which, as implied in the question, the Commission are making with their labours in that field. My right hon. friend is, however, in consultation with the chairman of the Commission on the position.

Free Choice of Dentist.

Sir JAMES GRANT asked the Minister of Health if he was aware that patients, in Health Insurance Section Approved Society No. 214, Co-operative Wholesale Society, were unable to obtain dental treatment by the dentist of their choice, as the society named refused to pay the scale of fees approved by the Dental Benefit Joint Committee on July 27th, 1926, to operate from Oct. 1st, 1926, to July 6th, 1930; and if he would take any action in the matter.—Mr. CHAMBERLAIN replied: I am aware that the approved society referred to has not recognised the scale of charges approved by the Dental Benefit Joint Committee, and a number of complaints have been received to the effect sugested in the question. The society cannot be considered to be infringing any existing statutory provision by limiting in this manner the members' freedom of choice of dentist, but the whole question on the steps to be taken to secure that insured persons entitled to dental benefit shall be able to obtain satisfactory treatment with proper freedom of choice of dentist, will receive consideration in connexion with the regulations to be made on the subject under the National Health Insurance Bill now before the House.

TUESDAY, MAY 1ST.

Treatment of Venereal Disease in Scotland.

Mr. BUCHANAN asked the Secretary of State for Scotland if he was aware that in certain counties in Scotland no facilities were maintained for the treatment of venereal disease; that 26 towns of a population of 10,000 and over had no clinic; that a number of sufferers were constantly shifting from place to place; and if, in view of the dissatisfaction arising, he would consider the establishing of a committee of inquiry into the whole question.—Sir J. GILMOUR replied: While in certain counties in Scotland there are no centres for the treatment of venereal disease, there is no county in Scotland that is without facilities for such treatment, either at a centre situated within its borders or by arrangements with another local authority. With regard to towns of a population of 10,000 and over the position is as stated in my reply of April 17th. I am aware that a certain number of persons suffering from venereal disease may shift from place to place and, indeed, for one important class of persons who frequently move—viz., sailors—treatment facilities have been specially provided in the principal ports. As I have stated in my previous answer already referred to, the development of venereal disease schemes in all areas is being carefully watched and reviewed by the Scottish Board of Health, and in connexion with the Budget proposals I have under consideration the whole position of local administration in Scotland. I do not think that at present any good purpose would be served by the appointment of a committee of inquiry such as the hon. Member suggests.

Royal Veterinary College, London.

Capt. CROOKSHANK asked the Minister of Agriculture whether his attention had been called to the state of the buildings of the Royal Veterinary College in London, some of which had been condemned by the London County Council, and to the consequent difficulties with which the College was faced in carrying on the work of assisting agriculture through the spread of veterinary science; whether he was aware of the grants made by the Governments of all other European countries towards veterinary science; and whether it was the intention of the Government to make any grants from the Development Fund, the Empire Marketing Board Fund, or from any other funds at their disposal, to assist in rebuilding the Royal Veterinary College in London, and to help the further spread of veterinary knowledge.—Mr. GUINNESS replied: I am well acquainted with the unsatisfactory condition of the buildings of the Royal Veterinary College and of the consequent difficulties under which the College labours; both my predecessor and I have conferred with the governors of the College on the subject. The governors are endeavouring to obtain the necessary funds to rebuild the College, and the Ministry has promised a grant of £35,000 on a £ for £ basis towards the funds which the governors are raising. I have no exact information as to the extent of the State grants made to similar institutions on the continent, but my hon. and gallant friend may rest assured that I appreciate the importance of this subject, and will do everything in my power to assist the College.

Vagrants and the Spread of Small-pox.

Mr. GRUNDY asked the Minister of Health (1) whether, in consequence of the epidemic of small-pox, he had instructed boards of guardians to adhere strictly to the provisions with regard to the disinfection of the vagrants' own clothes; and whether any instructions had been issued by him that these clothes, when taken away at night, should not all be bundled together; and (2) whether he had instructed boards of guardians to adhere strictly to the provisions with regard to the provision of warm baths; and whether any special instructions had been issued that nightshirts and towels should be washed before being given to each separate person.—Sir KINGSLEY WOOD replied: I am sending the hon. Member copies of the circular letters recently issued to boards of guardians in consequence of the epidemic of small-pox. Apart from these no special instructions have been issued, but the guardians are fully aware of the regulations in force, and the officers of my department would, as occasion might require, draw their attention to any necessary improvements in the arrangements of the several casual wards. As at present advised, my right hon. friend sees no ground for further action on his part.

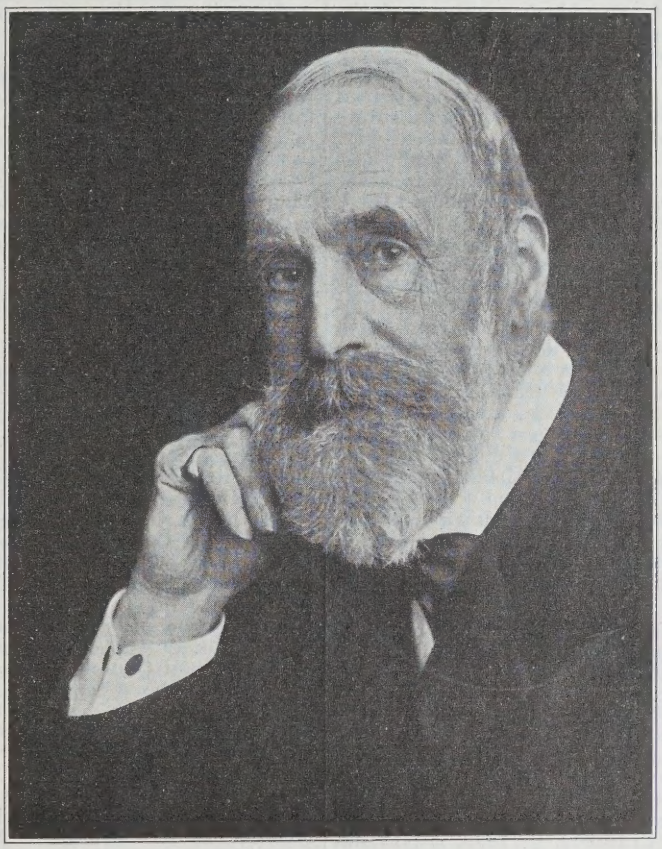
MEDICAL VISIT TO DENMARK.—The summer meeting of the University of Durham Medical Society took the form of a visit to the University and Hospitals of Copenhagen, from March 31st to April 6th. The party consisted of 45 students and members of the staff of the Newcastle Medical School, and the visit was arranged at the invitation of the Danish Students' National Union and the Medical Faculty of the University, with whom (H.B.M.'s Chargé d'Affaires) Mr. Millington Drake and Dr. Vincent Naeser had coöperated. The welcome given to the party was most cordial. On March 31st and April 2nd meetings were held at the Rigshospital. Prof. Knud Faber, in a lecture on the Medical Curriculum in Denmark, said that the course of study lasted seven years, and was always followed by two years' residence in hospital. One of the chief features of the student's career was the weeding-out process which took place in the third year, at the end of the courses in anatomy and physiology, and after some preliminary hospital work. More than a third of the students were rejected at this stage. Prof. Faber also gave a clinical lecture on Undulant Fever due to infection by *Bacillus abortus*, a disease which has been recently recognised as very prevalent in Denmark. Prof. Christen Lundsgaard followed with a lecture on Arterio-sclerosis, including an account of his own research into the subject, and Prof. V. Schaldemose gave a demonstration and operated in the big surgical amphitheatre of the hospital. Prof. C. E. Bloch lectured on Vitamins, showing cases of xerophthalmia and describing an epidemic of this deficiency disease in Denmark in 1918; whilst Prof. A. Krogh gave an address on Capillary Physiology, illustrated by the cinematograph. The remaining days were devoted to Prof. S. Monrad's Hospital, the Bispebjerg Hospital, the Finsen Institute, and the Serum Institute, where Dr. Thorvald Madsen received the party and gave a lecture. An unusual meeting was held on the outward journey on the S.S. *Arcturus* when Dr. J. C. Spence, the president, took the chair, and Mr. Rutherford introduced a discussion on Sea Sickness in which Captain Hjelt and many other speakers described their experiences and theories.

Obituary.

SIR WILLIAM CHURCH, BART., K.C.B.,

LATE PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

WE regret deeply to record the death on Friday st, April 27th, of Sir William Selby Church, which curred at his country house, Woodside, Hatfield, the ninety-first year of his age. He was a fine ponent of medicine, a judicious counsellor in various rections where the developments of science and the blic and professional interests were connected, and magistrate and county councillor brought all this pacity of judgment and impartiality to the conduct his country's airs. His quali- s of wisdom, firm- ss, and fairness d gained for him e high regard of all er more than half century of steady assuming work. William Selby urch, truly a Vic- ian in that he as born a few nths after the cession of the great ueen, was the ond son of John urch, also of odside, Hatfield, his wife Isabella, e daughter of orge Selby, of vizell House, rthumberland. He s educated at rrow, where he ained to a high ce in the school, ile becoming one the prominent ng cricketers of generation, for represented rrow at the ional game from 53 to 1856, being tain of the eleven the last year. oceeding from rrow to Univer- y College, Oxford, obtained a first ss in the natural ence schools, and rtly afterwards s appointed Lee ader in Anatomy, a university post which ried with it a studentship of Christchurch, and this society he was a Fellow for the nine years owing his graduation. Deciding to enter the dical profession, he joined the school of St. Bartholo- w's Hospital, and after qualification as L.R.C.P., s appointed lecturer in the school in comparative tomy. He graduated at Oxford in medicine in 4, and was appointed assistant physician to the pital in 1867, among his senior colleagues on the ff being Savory, Paget, Holden, Farre, and Southey. 1868 he proceeded to the M.D. degree at Oxford, l was elected F.R.C.P. Lond. in 1870. In the tter of obtaining quick charge of beds at S. Bartholomew's Hospital Church was fortunate, in his case the protracted delay which marked the eer of several of the distinguished physicians who owed him upon the staff was not incurred, and in 4 he became full physician to the hospital, a ition which he enjoyed for 28 years before retirement under the age rule, when he was appointed consulting physician. He was consequently associated as assistant, full, and consulting physician with St. Bartholomew's for over 60 years, and, save for a brief period of office at the Victoria Park Hospital, he served that charity only as a member of the honorary staff. As a physician and as a teacher he was systematic, diligent, and thorough, but a reserved nature, or rather, perhaps, manner, led to his actual instruction being more appreciated by those closely connected with him, as clerk or house officer, than by the students who attended his formal lectures and demonstrations. He was insistent upon the value of accurate notetaking and of regular attendance at autopsies.



SIR WILLIAM CHURCH.

Photograph by Elliott & Fry.

Dr. Morley Fletcher, senior physician to St. Bartholomew's Hospital, sends us the following estimate of Sir William Church, which gives an excellent picture of the dead leader. He writes: "Sir William Church was no longer on the active staff of St. Bartholomew's Hospital when I was appointed assistant physician, but I had been associated with him for some years as a member of the teaching staff and later as medical registrar. My first meeting with him was as one of his clinical clerks and two years later I was his house physician, and I feel that I owe much to his fine clinical teaching. He was not a man of many words and was by no means discursive at the bedside, but if asked questions he would respond and discourse freely on the point under discussion. Perhaps the students were inclined to be overawed by his commanding presence and his somewhat brusque manner, and I think he was at his best with his house physicians and I have often compared notes with others who held this post under him of whom no less than 46 served under him during his unusual tenure of office as full physician—no less than 28 years. There has been a general agreement among us that he was a wonderful clinical teacher for senior men. His power of diagnosis was remarkable; he abhorred guessing and his opinion on a case was always based on a thorough and careful examination and the diagnosis, when made, was almost invariably correct. He never obtained or took steps to obtain a large practice among the public, but his advice was eagerly sought by and freely given to members of the medical profession. Especially was he a fine morbid anatomist, and for years performed the medical post-mortem examinations at the hospital. The records so carefully drawn up by him are an evidence of his devotion to this important department of medicine. He expected his clinical clerks to be regular in their attendance in the post-mortem room and, in the wards, he would

discuss with them what they had seen there. And it was rare that he should be absent from his rounds in the wards, though it was always recognised that on Derby Day and during Ascot week he would not put in an appearance. The Medical School of the hospital owes much to him; he was chairman of the finance committee for many years, and was instrumental persistently in furthering the interests of the school. To individuals seeking his advice—and many did so—he was indeed a wise counsellor; to those in doubt as to the right course to pursue in some matter of difficulty he would quietly listen and then with sound judgment and in a few words give the desired help. His love of sport, exemplified in his early skill as a cricketer, came out in his proficiency as a skater. It was his delight whenever possible to skate, and generally he could be found skating with members of the skating club at the Toxophilite Club in Regent's Park. He was one of the oldest members of the club and a bold and skilful skater. He kept this sport up until comparatively late in life, enjoying it with the keenness and enthusiasm of a boy. Church will be greatly missed by many whom he has helped with his wise and kindly advice. His absolute sincerity and honesty of purpose were combined with sound judgment and clear-sighted vision, and these qualities rendered him invaluable in the important positions he held during his long and honoured life."

To Dr. Morley Fletcher's estimate there may be added the testimony of an actual though junior colleague of Sir William Church on the hospital staff. "It is impossible," he writes, "to over-estimate the good influence exercised by Church at St. Bartholomew's. There was, as it happened, at the time when he arrived from Oxford, urgent need to provide new buildings for the accommodation both of patients and students, and here he was in the front as an adviser full of wisdom and common sense, always open to reasoned argument, and therefore an admirable colleague and an ideal chairman of a committee. As a physician all his practice was based upon the constant study of morbid anatomy, and a visit to the post-mortem room invariably prefaced his attendance in the wards. He was a first-rate clinician and a sound and patient teacher whose views were always held in the greatest respect by his students and house physicians."

From such personal verdicts upon Church alike as man of science and man of affairs we can understand how he came to be called to the highest positions in his profession, and to discharge the duties finely. At the Royal College of Physicians of London, of which at the time of his death he was the senior Fellow, he had been an examiner on many occasions from 1874 onwards. He was elected on the Council in 1888 and was a Censor in 1890 and 1891; he delivered the Harveian Oration in 1895, became Senior Censor in the following year, and was elected President in 1899, a position which he held for five years, following Sir Samuel Wilks in the chair, and preceding Sir Richard Douglas Powell. His connexion with the Royal Society of Medicine was no less important. He had served as President of the Royal Medical and Chirurgical Society in 1893 and 1894, this term of office corresponding with the unexpired period resulting from the death of Sir Andrew Clark, so that when 14 years later the great amalgamation of the medical societies of the metropolis took place his election as first President was alike a recognition of his outstanding position and a reminiscence of past services. All Church's services to the Royal Society of Medicine were rendered in anxious times, for they followed immediately upon the period when the move was made, through the foresight of John MacAlister, and the generosity of Andrew Clark, from the small premises in Berners-street to the fine house in Hanover-square. In the subsequent establishment at 1, Wimpole-street, as the centre around which are amalgamated the greater number of the metropolitan medical corporations, Church's counsels were in frequent request, and he was president of the Society from 1908 to 1910. We have Sir John MacAlister's testimony that but for Church the amalgamatio the societies might have been deferred for y even if it was bound to come, but, as president o Royal College of Physicians at the time, he arra that a small organising committee of which he a wards became chairman should meet at the Col and from that time forward things proceeded swi

Sir William Church served on the Royal Commis on Vivisection appointed in 1906, that on the and Treatment of the Sick and Wounded in the S African War appointed in 1901, and that on Ars Poisoning appointed in the same year. The re of the Commission on the Care and Treatmen the Sick and Wounded, made its appear the week when Queen Victoria died, and had important decision to make as to whether the me and hospital arrangements during the South Af war had broken down, and whether there was justification for the statements that there had general or widespread neglect of the wounded. report was brief, was signed by all the five missioners, and the impression derived from perusal was that it was able, comprehensive, fair. The suggestions made by Sir William Ch and his colleagues with a view to remedy the de in the Royal Army Medical Corps, as revealed b the Commission, have since been largely follo The Commission on Arsenical Poisoning was a small one, presided over by Lord Kelvin; it appointed to inquire into the outbreak of peripl neuritis in the Manchester hospitals and poo infirmaries, which Dr. E. S. Reynolds and medical men and chemists had attributed to presence of arsenic in beer. The report was si by all six Commissioners and led to recommenda as to improvements in the official control over purity of food, and further recommendations a the proportions of arsenic in food which would held to constitute an offence under the Sale of and Drugs Act.

For King Edward's Hospital Fund for Londo William Church did especially valuable work, over a long period he acted as chairman of Distribution Committee, a position which made the virtual steward of vast charitable donati those who served upon the Committee with him not readily forget the pains which he took to d the allocation of grants in accordance with the recognition of the diversified claims.

Sir William Church wrote little beyond comm cations to the *Transactions of St. Bartholom Hospital*, of which he was for some time the editor, but he was the author of a brief contribu to Allbutt and Rolleston's "System of Medicine collaboration with Prof. W. Bulloch, on rheu fever. This is an excellent piece of writing, certain contributions to debates before the Medical and Chirurgical Society, circulated pamphlets, had the same careful grasp of subjects. But in the Harveian Oration he sh that he had a full and scholarly ability to when the occasion called upon him, for Chu description of the rise of physiology in England a fine literary performance.

The honours that fell to him were many. His University, and those of Glasgow and Manche made him D.Sc., of the University of Durham he D.C.L., he was created baronet in 1901, and rece the K.C.B. in 1902. He married Sybil, daught Mr. C. J. Bigge, of Linden, Northumberland, they had two sons, the elder of whom was k in the recent war, while the younger succeeds t baronetcy.

JAMES ALEXANDER MACDONALD,

M.D., M.Ch. R.U.I., LL.D. Belf.,

CONSULTING PHYSICIAN, TAUNTON AND SOMERSET HOSPI

A MEMBER of the medical profession who have been known to an unusual number of professional colleagues died last week in the p of Dr. J. A. Macdonald, the veteran worker fo cause of medicine through various offices in

tish Medical Association, holding almost every ce. He had been a member of the West Somerset nch Council from 1894 onwards, and had acted as representative for the past 25 years, holding office president of the branch in 1899 and again in 1926. recognition of his work for the profession in the st of England he was elected an associate member he Dorset and West Hants branch. He became a mber of the Central Council in 1906 and soon after- ds was elected chairman of the Representative ly in succession to Sir Victor Horsley. He held office for three years and was then chosen to ceed Mr. Edmund Owen as chairman of Council. retired from that position in June, 1920, after ring for ten arduous and eventful years, which uded the Insurance Bill crisis and the whole iod of the war. He was elected a vice-president he Association at the Belfast annual meeting in 9, held office as president of the Section of Medical iology at the London meeting in 1910, and during Birmingham meeting in 1911 the honorary degree LL.D. Birm. was conferred upon him. The ociation's gold medal of merit was awarded him 1913. In the following year he visited at the uest of the Association the New Zealand, Australian, some of the Far Eastern branches, and he acted in as ambassador of the parent body to Overseas nches when he visited South Africa soon after nquishing the chairmanship of Council. These ts were greatly appreciated by all members of the nches and did much to bind closer together the ociation at home and overseas. During his South ican tour in 1920 the occasion was taken to set foot an appeal for a testimonial fund in recog- on of Macdonald's long and distinguished service, the presentation was made to him during the vcastle annual meeting by Sir Clifford Allbutt, outgoing president. From 1920 onwards donald was chairman of the Journal Committee; was work which made a strong appeal to him, he was admirably equipped for it by tempera- t and experience. His loyalty to the *Journal* its staff was made plain every year when he sented the committee's report to the Annual presentative Meeting.

lacdonald personally exercised great influence by quiet genial demeanour, but his easy-going manner cealed great shrewdness and independence of d, and when his mind was made up to what he ught was right, forcible argument was needed to ke him change his opinion. He was a pillar of ngth to the British Medical Association in difficult es, and the medical profession owes him a great t.

HENRY LOUIS POWELL HULBERT, M.D. CAMB., D.P.H.

r. Hulbert, who died on April 18th at Grasse, he French Maritime Alps, after a long period of cement and ill-health, was in his fifty-seventh r. He was a son of Canon C. A. Hulbert, was n at Slaithwaite (Yorks), educated at Charter- se and Trinity College, Cambridge, entering St. tholomew's Hospital for his medical studies. er qualifying in 1901, he remained for a year at hospital as house physician, and prepared himself the School Medical Service by experience of rs at the Stockwell Hospital (M.A.B.) and Croydon sation Hospital, and of administration in an Essex l district and in Manchester. In 1906 he was ointed school medical officer to the county of nthamptonshire. His work there brought him close contact with teachers for whom he developed esteem which was reciprocated by them, and in will he made a substantial bequest to the county cation committee to be used for the benefit of school-children of the area. In 1911 recurring cks of pleurisy obliged him to winter in the Swiss s, and the enforced rest gave him the opportunity vriting the life of his uncle, Sir F. S. Powell, t., the Parliamentary sanitarian, a book which cts something of the mind of the biographer. During the late war he returned to active medical work, becoming divisional sanitary officer of the 61st (S.M.) Territorial Division, and later commanding the 43rd (Lowland) Sanitary Section, but unfortunately his health again compelled his retirement from practice. Leisure, however, meant for Hulbert the continuance of his earlier study of Latin and Greek literature, and of Plato in particular. He was much interested in art and had many artists among his friends, besides being himself an excellent colourist and water-colour painter. Loyalty to his school and college kept him in touch with a large circle of his former associates, who valued the old-fashioned charm and literary flavour of his letters. Since his retirement he lived a very quiet life with his wife, a daughter of the late Mr. Waring Bardsley, at their villa at Grasse, where he bore with philosophical calm the increasing discomforts of declining health. His death will come as a reminder to his old friends of a broad and smiling figure which embodied a spirit of equal breadth and humour.

WE have to record the death of RICHARD FRANCIS LISTER, M.R.C.S. Eng., who was drowned on April 23rd whilst yachting off Cherbourg. A son of the late Lieut.-Colonel Arthur Hugh Lister, R.A.M.C. (T.), C.M.G., he was educated at Lancing and at Trinity College, Cambridge. Two and a half years ago he entered the London Hospital, where his younger brother is a student, and in January he completed his medical course by taking the Conjoint qualification. At the end of March he became clinical assistant in the ear, nose, and throat department of the hospital, and he was to have returned there at the end of a short holiday at sea. He was a keen member of the United Hospitals Sailing Club.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 49 cases were considered and £659 voted to 41 applicants. Since the beginning of the year £2862 has been made in grants to urgent cases of distress. The demands for help increase and subscriptions are very urgently needed; they should be sent to the hon. treasurer, Sir Charters Symonds, at 11, Chandos-street, London, W. 1. The following are notes on a few of the cases relieved at the last meeting:—

M.D. At the age of 76, with his wife blind and suffering from cancer, and without a penny saved, the applicant suddenly found himself out of employment. For the last seven years he had been an assistant in a practice, but owing to the death of the principal, and the sale of the practice, the work had terminated. No provision had been made for old age or unemployment, as ever since 1912 the doctor had not been able to earn more than £300 a year, and it had been impossible to save on such an income. Before then he had been in regular practice and had educated two sons for the medical profession. This had naturally been a strain on his income at that time. The eldest son died during the war and the youngest is delicate and is struggling to keep himself going. In addition, there are two daughters to be educated. The doctor is willing and only too anxious to work, but at the age of 76 it is impossible to find employment. He will apply for the old-age pension. Voted £40.

Widow, aged 69, of L.R.C.P. The applicant's husband died early this year after a long illness, leaving her penniless. He was employed as a salaried assistant in a practice, and on his decease the widow received only £35, being the salary due to the date of his death. The sale of the furniture and a small gift of £20 has brought her total capital up to £150. She is now living with her niece, who is the wife of a clergyman who has only his stipend to depend on, and they are therefore unable to support her. Voted £36.

Widow, aged 77, of M.R.C.S. Since the death of her husband in 1884 the applicant has maintained herself as companion-housekeeper. Now at the age of 77 she is unfit for work and her only income is the old-age pension of £26 a year. Voted £36.

DONATIONS AND BEQUESTS.—William Vaughan Roberts, L.R.C.P., L.R.C.S., Blaenau Festiniog, after other bequests, left £1000 to provide a scholarship tenable at either Aberystwyth or Bangor College, and the ultimate residue to the Blaenau and Festiniog and District War Memorial Hospital.—The Manchester Royal Infirmary has received a legacy of £2646 from the late Miss Annie Latham and £1327 from the late Miss J. M. Jackson.—The Royal Manchester Children's Hospital has received £1000 from the executors of the late John G. Litton.—The Rev. William John Pinckney, St. Leonards-on-Sea, on the death of his wife, gave £1000 each to the Alexandra Home for Chronic Invalids, St. Leonards-on-Sea, the Buchanan Hospital, St. Leonards-on-Sea, and £700 to the Borough of Hastings District Nursing Association.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a recent examination the following candidates were approved :—

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

Part I.—Oliver Chance, S. J. Dikshit, F. J. Farr, C. W. S. Fernando, N. P. Henderson, S. A. Jabbar, Leila K. Keatinge, D. F. Lawson, W. P. Philip, H. C. Pillsbury, B. K. Roy, Tokue Takahashi, R. N. Tandon, E. Thorpe, E. J. E. Topham, A. K. S. Venkatachala, J. D. H. Wearing, and F. G. Wood.

Part II.—Nessim Abu-Saif, J. H. Baird, J. J. N. Daniels, W. E. Donaldson, Frances Dooley, Emily L. Franklin, J. F. Grant, S. A. Jabbar, S. L. Mucklow, R. G. Murray, S. D. S. Park, Mostafa Ragheb, W. G. Rich, H. T. Rymer, C. F. O. White, and John Wilkie.

UNIVERSITY OF LONDON.—A course of four lectures on the Human Kidney and the Physiological Study of Human Urine will be given by Prof. J. B. Leathes, F.R.S., at Guy's Hospital Medical School, St. Thomas's-street, S.E., on May 15th, 16th, 22nd, and 23rd, at 5 P.M. Prof. M. S. Pembrey, F.R.S., will take the chair at the first lecture. Admission is free, without ticket.

At a recent examination at the University of London the following candidates were successful :—

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

With Special Knowledge of Psychiatry.—A. W. H. Smith and F. O. Walker.

With Special Knowledge of Mental Deficiency.—N. H. M. Burke and J. N. Jacobson.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful in the undermentioned subjects :—

Surgery.—G. E. Bent, Manchester ; A. R. D'Abreu, Leeds ; D. Jacobson, St. Bart.'s Hosp. ; D. K. Reynolds, King's College Hosp. ; I. O. B. Shirley, St. Thomas's Hosp. ; and A. E. Vawser, London Hosp.

Medicine.—H. B. Blaker and H. T. Ince, St. Mary's Hosp. ; H. T. Rylance, Middlesex Hosp. ; and W. Ziv, Bale and London Hosp.

Forensic Medicine.—B. Elliott, Durham ; J. H. Johnston, St. Bart.'s Hosp. ; N. H. Kettlewell, Bristol and Middlesex Hosp. ; and E. A. Lipkin, Liverpool.

Midwifery.—A. E. Gibbs, London Hosp. ; and C. C. F. White, Guy's Hosp.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery and midwifery : B. Elliott, H. T. Ince, D. Jacobson, D. K. Reynolds, H. T. Rylance, and I. O. B. Shirley.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary comitia of the College was held on April 26th with Sir John Rose Bradford, the President, in the chair. The following Members of the College were elected Fellows :—

Carlton Oldfield, Newman Neild, Vincent Sutherland Hodson, Sydney Arthur Owen, John Bright Banister, Laurence Ball, Rodolf Charles Wingfield, William Willis Dalziel Thomson, Thomas Beaton, Wilfred John Pearson, Neil Hamilton Fairley, Geoffrey Marshall, Ernest Basil Verney.

Nominated by the Council under by-law XXXVIII (*b*):—

Edward Mellanby.

The following candidates were elected Members of the College :—

Harold Awrounin, Douglas Charles Beaumont, Mona Margaret Blanch, The Hon. Olive Burton Buckley, George Campbell, Bernard Maule Clark, Arthur Edgar De Chazal, Ewen Thomas Taylor Downie, James Gilbert Falconer, Kenneth Alexander Hamilton, Tom Allistair Falconer Heale, Leslie Charles Hill, Arthur Sturgess Hollins, Thomas Cecil Hunt, Bertram Humphreys Jones, Abdulla Karmally, Samuel Maurice Katz, Alice Margaret Craig Macpherson, John Kempson Maddox, William Hotson Palmer, Jean Lilian Smith, and Richard Robertson Trail.

The report of the Committee of Management of the Examining Board in England of the Royal College of Physicians of London and the Royal College of Surgeons of England, that it was desirable and practicable to hold a clinical examination in obstetrics and gynæcology in connexion with the final examination in midwifery for the diplomas of L.R.C.P., M.R.C.S., was adopted.

A report of the Committee of Management, recommending that the College should conform to the practice of other licensing bodies with regard to the period at which the professional curriculum was to be regarded as beginning, was adopted.

Licences to practise were conferred upon 156 candidates (131 men and 25 women) who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and have complied with the necessary by-laws of the College. The following are the names and medical schools of the successful candidates :—

M. E. Albury, Cambridge and St. Thomas's ; B. A. J. Arthure, Birmingham and Charing Cross ; R. E. Artrick, Univ. College ; Mabel A. Baker, Royal Free ; Ellen M. Barnes, Univ. College ; N. R. Barrett, Cambridge and St. Thoma Charlotte Belinky-Raginsky, Charing Cross ; A. D Bell, Oxford and St. Thomas's ; Ruth Bocock, R Free ; H. H. Boyden, St. Bart.'s ; J. M. Bucha Middlesex ; W. Buckley, Cambridge and St. Bar F. Bush, Cambridge and Univ. College ; G. Camp St. Thomas's ; G. C. Campbell, Guy's ; A. G. Carmich Middlesex ; R. E. P. Cohen, Birmingham ; E. T. C beare, Guy's ; N. E. Cook, St. Bart.'s ; A. D. W. Co S. Mary's ; B. W. Cooke, St. Bart.'s ; R. W. Coo Middlesex ; T. V. Cooper, Westminster ; E. Cor London ; J. E. Crooks, Guy's ; A. Dala, Liverp C. H. Dale, St. Bart.'s ; T. C. Dance, Birmingham ; T Davie, Cape and Liverpool ; Mona C. Davies, Cardiff Charing Cross ; R. G. de Kock, Cape and Guy's ; C Dobson, Durham ; W. J. G. Drake-Lee, Cambridge St. Thomas's ; L. L. Eksteen, Liverpool ; W. A. Ellis Cambridge and St. Bart.'s ; C. Emery, Univ. Coll R. B. Floyd, Cambridge and Machester ; M. Fran St. George's ; J. P. Fraulo, Guy's ; G. H. Gange, C bridge and Middlesex ; A. P. Gaston, St. Bart.'s ; Y Gimpelson, St. Mary's ; P. S. Gitlin, Guy's ; J. C. Gor Cambridge and St. Bart.'s ; S. E. Goulstine, Durh Tatiana Gourlande, Moscow and St. Mary's ; G. N. G St. George's ; A. E. Handousa, Cairo and St. Bar H. N. W. Harley, Guy's ; G. A. S. Harris, St. Bar M. R. W. Hart, Madras and St. Bart.'s ; J. S. Hensr Cambridge and St. Bart.'s ; A. N. Hobbs, St. Bar R. Hodkinson, Cambridge and St. George's ; L. Hoffr St. Bart.'s ; E. J. Horn, London ; Kathleen Horne, Le M. C. Hounsfield, Cambridge and St. Bart.'s ; Murie Hulke, Univ. College ; T. A. A. Hunter, Cambridge London ; J. G. H. Ince, Univ. College ; S. D. Woodroff, King's Coll. ; Janet D. E. Yo Royal Free ; R. A. Zeitlin and J. S. Zidel, St. Bart and S. Zuckerman, Univ. College.

THE LATE DR. W. P. BRIGGS.—Dr. William Pe Briggs, who died on April 20th, after a short illness, practised at Aspatria, in Cumberland, for nearly 50 ye He took the Scottish Conjoint diploma in 1877, hav studied medicine at the University of Glasgow and Anderson College. After a house appointment at Glasgow Royal Infirmary, he went into partnership w the late Dr. William Hodgson, and as soon as the Aspa Urban Council was created, he became its medical offi of health. A colleague writes of him that he had " enthusiasm that never waned, a cheerfulness that seld shrank, an interest in life that was always present. ungrudging devotion to his profession, and his own s respect, made him loved and respected, and he will mourned as a man who carried out private and pu duties conscientiously, scrupulously, independently, fearlessly." Dr. Briggs was 72 years of age, and survived by a widow and the eldest son of her f marriage.

Dr. Isaac Alexander Davidson, of Antrim-road, fast, is, we are glad to be able to state, alive and in the ive practice of his specialty. The notice of his death ich appeared in THE LANCET of April 14th was based upon orrect information received from our local correspondent, led by the similarity between the names of Dr. I. A. vidson, ophthalmic surgeon, and his cousin, Dr. Thomas Davidson, a general practitioner, of 13, Clifton-street, fast, whose death occurred on March 28th. We desire give every possible publicity to the correction.

CHADWICK PUBLIC LECTURE.—A lecture on light, Natural and Artificial, and its Use in Modern licine, illustrated by lantern slides, will be given by Major lter Elliot, M.P., on Tuesday, May 15th, at 8.15 P.M., he House of the British Medical Association, Tavistock-are, London, W.C.

ABERDEEN UNIVERSITY CLUB, LONDON.—The enty-ninth half-yearly dinner will be held at the Trocadero taurant on Thursday, May 17th. The secretary's address , Addison-gardens, W. 14.

'CARNIVAL BEDS."—Sir Percival Bower has veiled tablets above three beds in the Queen's Hospital, mingham, recording that they were endowed by the zens of Birmingham with money raised by the University dents' Carnival. These carnivals have produced a total £25,000 since 1922.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.—ourse of six lectures on Mind in Nature is being given 5.30 P.M., on Tuesdays in May and on June 5th, by f. C. Lloyd Morgan, F.R.S. A course of four lectures the Philosophy of Religion will be given by Prof. Clement J. Webb, on Wednesdays, May 23rd, 30th, June 6th, and h, at 4.45 P.M. Both courses will be given at the Univer- of London Club, 21, Gower-street, W.C.1. Syllabuses l particulars may be had from the Director of Studies, Kingsway, London, W.C. 2.

ROYAL SOCIETY OF MEDICINE.—It has been decided widen the scope of the Associateship. A few years ago Associateship was instituted in order to encourage able juniors in the profession to take advantage of the vileges of this Society, and the position was at first ricted to qualified members of the medical profession. a general meeting of Fellows, recently held, has amed the by-law in regard to Associateship as follows:—

The Council shall be and is hereby empowered from time ime and at its sole discretion to elect medical, dental, and erinary practitioners (whether British or otherwise) who hin five years of their first professional qualification apply election, to be non-corporate Associates of the Society."

s means that promising young odontologists and erinary surgeons can now apply for Associateship and lected by the Council of the Society if they are approved. should be added that Associateship is only available to iors within the first five years of their qualification, as finishes automatically at the end of that time. The ociate has the right to attend scientific meetings and to the library, though he may borrow one book at a time y, and when he has paid three annual subscriptions may, lected to the Fellowship, be admitted without payment ntrance fee.

WORK OF THE NATIONAL BABY WEEK COUNCIL.—e display of moving pictures occupies an increasing re of the National Baby Week Council's activities. The rly issued annual report mentions eight films which were l in demand during the year. The most recent of these "Black Lake Home," depicting the convalescent home the wives and babies of professional men which has its s in Sir James Barrie's old home at Farnham, and "Who to blame?"—a propaganda film. Health plays and tern lectures were also a feature of the year's work. pecial film display was staged at the annual conference, n the whole evening's programme consisted of health s, and some 600 people attended. The points selected the Council and recommended for special attention in s year's local and national programmes are: (1) immunisa-n as a means of protecting young children against ase; (2) prevention of maternal mortality; (3) new elopments in maternity and child welfare work. Baby ek is to be celebrated as usual during the first week in y, and a conference will be held on July 4th, 5th, and 6th, n the following subjects are to be discussed: The ative Value of Intensive Methods Employed for the luction of Infant Mortality; the Causes and Prevention Maternal Mortality; the Requirements of the Unmarried ther and Her Child; the Place of Antenatal Care in Reduction of Maternal Mortality. This is to be followed an international child welfare congress to be held from y 8th to 12th in Paris.

GLASGOW UNIVERSITY CLUB, LONDON.—The annual summer dinner of this club will be held at the Trocadero Restaurant, Piccadilly, W., on Friday, May 25th, at 7.15 P.M. for 7.30 P.M. Sir Donald MacAlister will preside. Any Glasgow University men who, though not members of the club, desire to attend, should communicate with the hon. secretaries at 62, Harley House, N.W. 1.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—The Morison Lectures will be delivered by Dr. John Carswell at the College, on Monday, Wednesday, and Friday, May 7th, 9th, and 11th, at 5 P.M. His subject will be Psychology and Medicine.

MEDICAL SOCIETY OF LONDON.—The annual general meeting and conversazione, arranged for Monday, May 14th, has been postponed to Monday, May 21st. At 9 P.M. on this evening Sir Archibald Garrod will deliver an oration entitled Lessons on Rare Maladies.

TAVISTOCK-SQUARE CLINIC.—The annual general meeting of the Tavistock-square Clinic for Functional Nervous Disorders will be held in the form of a luncheon at the Hotel Russell, Russell-square, London, W.C., on Monday, May 21st, at 1 P.M. for 1.15 P.M.

ST. CYRES LECTURE.—The second St. Cyres Lecture of the National Hospital for Diseases of the Heart will be delivered by Prof. K. F. Wenckebach at the Barnes Hall of the Royal Society of Medicine, on Wednesday, May 16th, at 4.30 P.M. His subject will be the Heart and Circulation in Tropical Avitaminosis (Beri-beri). Tickets may be obtained from the secretary of the hospital, Westmoreland-street, London, W. 1.

HULL ROYAL INFIRMARY.—The annual report of this institution states that last year it treated just under 36,000 patients, or more than 10 per cent. of the population of the city. In addition the casualties exceeded 18,000 in number.

SHEFFIELD ROYAL HOSPITAL.—The board of management reports that the average daily cost of an in-patient last year was 7*s.* 4*d.*, a reduction of 6*d.* upon the preceding year. The yearly cost per occupied bed has fallen from £142 16*s.* 3*d.* to £133 5*s.*

FIRE AT WINDSOR HOSPITAL.—A fire which originated in a servants' room last week destroyed two wards of the King Edward VII. Hospital at Windsor. Fortunately it broke out in the afternoon and the 120 patients, six of whom had been operated upon earlier in the day, were removed safely. The hospital was rebuilt in 1909.

MIDDLESEX CANCER HOSPITAL.—During the past year 564 patients were treated, as compared with 621 in 1926, and they were given longer treatment. One-half of the beds in the cancer wing of Middlesex Hospital are now devoted to operable cases.

DEATH OF DR. J. L. RANKINE.—John Lawson Rankine, who died on April 19th, had for many years been medical officer of health for the rural district of Longtown in Cumberland, and held other appointments in the neighbourhood. He studied medicine at Guy's Hospital and took his M.R.C.S. Eng. in 1907, subsequently serving as house surgeon at the Dumfries and Galloway Royal Infirmary, and as clinical assistant in the Royal Eye Hospital, Southwark. After private practice at Mallsburn, near Bewcastle on the Border, and at Kirklinton, he took over the practice of Dr. R. E. Marwick, at Longtown. During the war he held a captain's commission in the Royal Army Medical Corps and served in the East. He leaves a widow with a son and a daughter.

WOMEN IN THE SERVICE OF HOSPITALS.—A conference, convened by the National Union of Societies for Equal Citizenship, will be held on May 8th, to discuss three aspects of this subject, notably (1) Opportunities for training of women medical students. (2) The appointment of women to paid and honorary medical posts in hospitals, and (3) the appointment of women on boards or committees of management of hospitals (including mental hospitals). The speakers at the conference, which will be held at Mary Sumner House, 24, Tufton-street, Westminster, from 2.30 till 6 P.M., will include Dr. Margaret Emslie, Miss C. Fulford (chairman, Fulham Board of Guardians), Dr. Graham Little, M.P., and Miss Eleanor F. Rathbone. Visitors' tickets (price 1*s.*), and all further particulars can be obtained on application to the N.U.S.E.C., 15, Dean's Yard, London, S.W. 1.
